All these facts are easily harmonized with our theory; for the man with strong passions finally exhausts his powers, and, as the enlargement always takes place very gradually, he may, as old age approaches, have an hypertrophy of this body. The very chaste man has little passion, because his virility is not of a high developmental character; he is of a sluggish, phlegmatic temperament; his generative powers are feeble, and, as a consequence, he has a greater tendency to revert towards the female type than a passionate, masculine man. He is constitutionally weak in this particular, and congenitally less highly developed. The reason the man of intense passion does not suffer from enlargement is because his organism is under the domination of a very highly developed sexuality, which is self-evident from simply reasoning from cause to effect.

Mr. John Adams§ "cannot doubt that there is some necessary connection between declension of the powers of the generative system and the enlargement of the prostate."

A curious coincidence in the developmental change taking place in these analogous organs of the male and female after the procreative faculty has ceased, is brought out in the author's paper|| on

* Medico-Chirurgical Transactions, vol. xliii., 1860, pp. 145-176.

‡ It is curious to note another of the opposite conditions which favor enlargement of the prostate, compared with conditions which favor cancer of the uterus, viz.: It has been maintained that celibacy favors the development of cancer of the uterus, though Mr. Lever considers that his tables, comprising one hundred and twenty cases of cancer of the uterus, afford a complete refutation. See his article in Med.-Chir. Trans., Lond., 1839, vol. iv. p. 271.

§ The Anatomy, Disease, etc., of the Prostate, London, 1851, p. 87.

|| "Deaths from Cancers occurring in Philadelphia from January 1, 1861, to

the proportion of sexes in deaths from cancer, with the proportion of women dying before and after the climacteric. It is there shown that 60.8 per cent. of all the women who die of cancer of the uterus have passed the climacteric period. The average age of all those who died of cancer of the uterus was 49.08 years. Cancer of the breast was still more fatal after the forty-fifth year, as 78.5 per cent. of the deaths from this cause were of persons above this age. The average age at death from cancer of the breast was 56.84 years. Of all the women dying of cancer, 28.66 per cent. die of cancer of the uterus. Women, being less highly developed* than men, are more liable to this developmental disease. We find in our table 2.32 females to every male dead from this cause.

M. Jolly, in his elaborate and exhaustive essay† of sixty-one pages on cancer of the prostate, considers that the rarity of the affection may possibly be a little exaggerated, though with all his assiduity he was able to collect only thirty-five reliable cases from the whole field of medical literature.

Professor Gross‡ says that cancer of the prostate is too rare and too little known to trace its history.

M. Tanchou§ found but five cases of cancer of the prostate among the 1904 men who died of cancer in Paris from 1830 to 1840. The proportion is 1 in 381 cases.

The writer, in his researches concerning cancer,|| found but two cases of cancer of the prostate body registered in the Health Reports of Philadelphia for the twelve years ending December 21, 1872. During this period, 788 men died of cancer in various organs. The proportion is 1 in 394 cases. One of these men was between 50 and 60 years of age at death, the other was between 70 and 80; both were natives of the United States.

M. Jolly† says, "Entre toutes les glandes, la prostate est une de celles qu'envahit le plus rarement le cancer. A une certaine époque, on avait même pensé que cet organe n'était jamais le siège de la dégénérescence, et c'est en France surtout que cette opinion a été défendue" (p. 377).

Jolly† (p. 592) gives the following table of particulars in the 35 cases he has collected:

The writer has brought forward several facts and arguments in the papers already mentioned, tending to show that the woman occupies an intermediate developmental or evolutionary position between children and men; in short, she is less highly developed than the man. It is also well known that females, when deprived of the domination of the ovaries, either by congenital absence, ablation, disease, or the natural cessation of the procreative function, take on some of the secondary sexual characters of the male, or, in other words, become masculine. Any of the same processes would operate to make the male effeminate. So we see that the female under such circumstances approaches the condition of the male, by a sort of progressional development, and the male, by a kind of retrogressional development, approaches that of the female; that is, they both tend to the intermediate sexual condition of hermaphroditism, the male being naturally above it, and the female below it, developmentally. One is reminded of Tennyson's¶ admirable philosophy in this.

This approach is not only true of the sexual organs, but also of the composition and functions of other parts of the body. Thus, in old age (second childhood) the blood was found by Dennis Le Caull, and Foedisch to contain a larger proportion of water than in ripe maturity, approaching in its composition to that of children in this particular. The temperature** of the aged is lower, and the pulse more frequent, than in persons of middle age, approaching also in this particular to the condition in childhood.

It is not difficult, then, to understand that the prostate body, which remains undeveloped in the male so long as the organism is under the domination of the reproductive organs (testicles), should begin to develop when this influence is removed. So in the woman, when the reproductive faculty is extinguished at the menopause, or by ablation or disease of the ovaries, the uterus, which is the analogue of a part of the prostate in the male, degenerates, shrivels up, and is reduced in size. The uterus in the female diminishes in size from the same cause that the prostate increases in size in the male, viz., the deprivation of the domination of the sexual organs (testicles or ovaries). It would be interesting in cases of enlarged prostate to inquire whether there is loss of, or diminished, sexual power or vigor, as confirmatory of this theory.

It is no argument against this theory that enlargement does *not always* occur in old age, as one might imagine from the statements of the authorities cited; for all males or females, even when deprived of the essential organs of reproduction, do not develop

¶ "Yet, in the long years liker must they grow;
The man be more of woman, she of man."

The Princess.

** See further in the writer's paper on "The Temperature of the Sexes an Indication of Development,"—*Philadelphia Medical Times*, November 8, 1873, p. 3.

secondary sexual characters of the opposite sex, though it is the rule for them to do so.

It is a rule, therefore, that enlargement of the prostate occurs in the aged (being indicative of decline in, or extinction of, the procreative faculty) for the same reason and under the same circumstances that atrophy of the uterus takes place in the aged woman; both indicating a developmental determination towards an intermediate (hermaphroditic) sexual condition, caused by the elimination of the domination of the essential organs of generation (testicles and ovaries).

This theory is strongly corroborated by the fact of the very great frequency of cancer of the uterus (of all the women dying of cancer, 28.66 per cent. die of cancer of the uterus), and the very great rarity of cancer of the prostate body (of all the men dying of cancer, only .27 per cent. die of cancer of the prostate).

Now, it is well known that cancer is a degenerative process or retrogressive developmental disease, and attacks the mammæ, or glandular organs, and the uterus, a muscular organ, usually after they have ceased to perform their destined functions connected with reproduction. This being true, it is curious to note that the prostate is more or less enlarged in from 20 to 35 per cent. of all men dying after the fiftieth or sixtieth year; yet of all the men who die of cancer, only .27 per cent. die of cancer of the prostate, it being more than one hundred times less frequent than cancer of the uterus. The conclusion is, therefore, that, cancer being a disease which attacks organs that are degenerating, and itself further degenerating and destroying them, *the enlargement of the prostate body is not a retrogressive but a progressive developmental evolution of a congenitally under-developed homologue of the uterus.*

The fact being established of the development of female organs and secondary sexual characters in old men, that is, a tendency towards hermaphroditism (which latter is an intermediate state between the separate male and female condition), is altogether in favor of an opinion which we have deduced from numerous observations, viz., that *the type of all diœcious species is sexually hermaphroditic*; that is, the man is as much above the type as the woman is below it.

We conclude, therefore, that *simple enlargement of the prostate body, far from being a diseased condition, is frequently, and indeed generally, but one of the exhibitions of the vibrations in the pendulum of developmental or evolutionary forces which determine and separate the sexes.*

PHILA., 2003 WALNUT STREET, December, 1872.

SO-CALLED PSORIASIS SYPHILITICA.

BY LOUIS A. DUHRING, M.D.,

Clinical Lecturer upon Diseases of the Skin in the University of Pennsylvania, and Physician to the Dispensary for Skin Diseases, Philadelphia.

MY object in the present communication is to ask attention to an error in nomenclature. A definite and accurate system of words is in reality of greater importance to the progress of a science

than the majority are willing to admit. Nomenclature is to the scientific circle what language is to the people. It is an essential, without which there exists no means of conveying clear and distinct ideas from one individual to another. All science demands this *system*, and the more intelligible and perfect it is, the more easily will a knowledge of the subject be imparted. The more accurate and definite it is made, the more refined and exact will the science become. Too much care and attention cannot be exercised in guarding the subject, whatever it is, from ambiguity.

Dermatology at the present day needs a thorough remodelling of its *vocabulary*. Year by year incorrect, loose, meaningless expressions have been allowed to enter the list, until it has become so burdened and complicated with superfluous terms that the student entering upon the study of this subject becomes at once confounded and lost in the phraseology.

Among the expressions which are commonly used to denote certain varieties of skin-disease are to be found a number of *compound words*, of which no more unfortunate example can be presented than the so-called "psoriasis syphilitica." This term, originally intended to express a variety of one disease, is a very bad one, for it is calculated to mislead as to the nature of the affection. Let us investigate more closely. What are we to understand concerning the disease by the term psoriasis syphilitica? What is its nature? and, possessing such a name, where should it belong in classification? What is the student expected to know when he hears this expression? He is aware, perhaps, of the existence of two separate diseases of the skin, psoriasis and syphilis; he knows that psoriasis usually shows itself in uniform characters, and that, on the other hand, syphilis may appear in many different forms. But now he hears of and sees a "psoriasis syphilitica," a syphilitic psoriasis, and he is at a loss to comprehend the nature of the disease. The question arises, is it a psoriasis, a psoriasis vulgaris, such as is seen every day in connection with a clinic for skin-diseases,—a psoriasis influenced and altered by the poison of syphilis, and hence syphilitic? Or, on the other hand, is it a manifestation of syphilis modified by the presence of psoriasis? Or, again, is it merely a cutaneous form of syphilis bearing a resemblance in appearance to psoriasis? The first of these suggestions, that it is a *bona fide* psoriasis changed by syphilis, would certainly be the more justifiable inference from such an expression as psoriasis syphilitica. But such is by no means the actual condition. The disease which really exists in the so-called psoriasis syphilitica is not psoriasis at all, but syphilis. *There is not a sign or trace of psoriasis present.* This infiltrated, partially papular and squamous form of syphilis has received the name psoriasis syphilitica simply from its resemblance in appearance to psoriasis, a disease with which, however, as just stated, it is absolutely in no way associated. If this then be true, it is very evident that the term is a misnomer. Such it is, and as such it should be discarded. It has crept into our nomenclature through carelessness, as many other loose expressions have

done, but so manifestly inaccurate and dubious is it, that no time should be lost in abandoning it for something more definite. Let a term be generally adopted which will afford some idea of what the disease really is. The morbid process is syphilis, pure, unalloyed, manifesting itself upon the skin. It is a syphiloderm of a squamous form: hence the expression squamous syphiloderm has at least the advantage of conveying a clear conception as to the nature of the affection. Why make use of a compound word, composed of the names of two diseases so widely different as psoriasis and syphilis, for the purpose of expressing a form of *one* disease? Psoriasis and syphilis are two distinct pathological as well as clinical processes, having nothing in common. Why use the word psoriasis at all? There is no psoriasis present. Two distinct diseases are here compounded merely because one affection occasionally happens to bear some likeness to the other. Syphilis is made an adjective to qualify psoriasis, a condition which *does not exist* in connection with the so-called psoriasis syphilitica. Now, in the first place, the name of a disease should *never* be used as an adjective. Nor should the name of an already well-known disease ever be employed for the purpose of describing another affection. A disease should possess one name, and that name be retained exclusively to represent that disease.

Psoriasis syphilitica is a meaningless and inaccurate expression, and inevitably causes confusion and doubt in the mind of the student. Such terms are most disastrous to the advancement of dermatology, and should not be suffered to remain in our *language*. It is proper time that attention be given to the purifying of our nomenclature, and that all ambiguous and superfluous terms be abolished. Let us at least make the attempt to adopt a system of expression which will convey some idea of the subject to the intelligent student.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. R. J. LEVIS.

Reported by JOHN B. ROBERTS.

EXCISION OF THE ANKLE-JOINT FOR CARIES OF THE ASTRAGALUS AND INFERIOR EXTREMITY OF THE TIBIA.

A BOY has been in the hospital some time with disease of the bones of the foot, which is much swollen and has a large number of sinuses, all apparently leading in the direction of the astragalus, though there is probably disease of the tibia also, for the lower end of that bone is much enlarged. It is impossible to determine how extensive is the caries in the vicinity of the joint, without making a complete exploration of the parts by cutting down upon them.

If the disease is limited to the bones immediately concerned in the articulation, it may be possible to retain the foot by excising the ankle-joint; but if the bones are extensively carious, and especially if the calcaneum is involved, some form of amputation of the foot at or above the ankle will be required; though conservatism will be an object of consideration, in order to give the patient all available utility of the member.

If it were certain that excision of the joint would be proper in this case, an incision would be made upon the external aspect of the foot, and the astragalus dislocated outwards; but as a thorough examination of the condition of the bones must be made prior to a decision as to the character of the operation to be adopted, a free incision is made directly across the top of the foot, from the external to the inner malleolus, freely exposing the interior of the joint. This incision necessarily cuts off, upon the dorsal surface of the foot, the extensor tendons and divides the anterior tibial as it becomes the dorsal artery of the foot; but care is taken to avoid injury of the posterior tibial, upon the integrity of which will depend the nutrition of the foot, if excision is to be finally performed. Examination of the parts thus exposed shows the entire astragalus to be carious, as is also the lower portion of the tibia, the end of which shall therefore be sawed off, after the other bone has been removed by the gouge.

The measure finally adopted will very much depend upon the condition of the calcaneum, for if this is healthy it will determine the performance of resection of the ankle, provided that the other tarsal bones are sufficiently free from disease to permit their retention. If these latter, however, must be removed, it can be left to form part of the stump of a Pirogoff amputation; but if it also is carious, an amputation of the leg above the ankle will be necessitated.

Fortunately, it is found that the disease is limited to the end of the tibia and to the astragalus, and that the other bones of the tarsus are perfectly healthy. After a careful removal, then, of all portions of diseased osseous structure, the foot will be brought up into apposition with the sawn end of the tibia and fibula, and sutures introduced to hold the tissues together constituting a complete excision of the ankle-joint.

Excision of the ankle-joint has not been very popular with surgeons, but in many instances exceedingly good results have been obtained after the operation. Dr. Levis mentioned a case, and showed a cast of the foot taken recently, where he had performed excision of the ankle fourteen years ago; and he believed it to be the first excision of that kind performed in this country. He stated that the girl was now able to walk gracefully, and even to dance upon the foot; for, although the ankle-joint is necessarily ankylosed, there has gradually been acquired a great latitude of motion between the other tarsal bones, so that the foot has regained a considerable amount of elasticity.

This boy, upon whom excision of the ankle-joint was performed six weeks ago, has been doing quite well since the operation; and, although he cannot yet bear his entire weight upon the foot, he has greatly improved in general health. There are here several sinuses leading to the joint, which render it probable that there may be some further caries of the bones, which, if present, will necessitate a slight operation for its removal before the patient will be entirely well; but it is certainly gratifying to think that the boy's foot was not sacrificed by amputation at the inferior third of the leg.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS, M.D.

Reported by J. B. ROBERTS.

PROLAPSE OF THE RECTUM CAUSED BY THE PRESENCE OF A VESICAL CALCULUS—LITHOTOMY—CURE OF THE PATIENT.

THIS little boy, four years of age, has had, since he was one year old, symptoms of cystitis; and the great straining during micturition, which has continued down to the present date, has caused an enormous pro-

trusion of the bowel. This prolapse of the rectum, having existed for about two years, has been out for three months past without replacement, which it is said cannot be effected, and it is now five and a half or six inches in length. The length of the protrusion is so great that it is exceedingly probable that a portion of the sigmoid flexure of the colon is involved in the prolapse, as well as the rectum.

Prolapse of the bowel may be partial, as where merely a part of the mucous membrane of the intestine is found projecting beyond the anus; or complete, as in this instance, in which all the coats of the tube protrude, from invagination of the lower part of the alimentary canal.

The habitual contact of the delicate mucous membrane with the air and the urine which dribbles over it, has induced inflammation, giving rise to redness of the parts and the secretion of a muco-purulent fluid: indeed, in such cases it occasionally happens that strangulation of the protruded bowel occurs, from the pressure exerted by the sphincter muscle; but this complication, fortunately, is quite infrequent.

The cause of the affection is usually the straining incidental to chronic diarrhoea or dysentery, ascariides, vesical calculus, and similar diseases, associated with a relaxed condition of the floor of the pelvis and the muscular structures about the anus. The history of this case shows that the boy has great pain in the region of the bladder, and is troubled with frequent micturition, being unable to retain his water longer than half an hour: hence it is probable that there is a stone in the bladder, which, from the straining consequent upon its presence, has been instrumental in the production of this enormous prolapse of the rectum.

Upon the introduction of the sound, there is perceived, without the least difficulty, a stone, lying low down, and situated, apparently, directly at the mouth of the bladder, which has undoubtedly been the exciting cause of all this trouble. In order, then, to cure the patient, the extraction of this stone is demanded, for as long as it remains in the bladder it is useless to reduce the prolapsed bowel, which would be again protruded immediately upon the occurrence of straining, which will continue as long as the calculus remains.

The protrusion of the rectum renders the performance of lithotomy somewhat difficult, as it interferes with the introduction of the finger into the bowel, compels the operator to cut directly for the staff, and renders the exercise of extreme caution necessary to avoid injury to the gut.

The bladder having been injected with tepid water, I proceed to perform lithotomy by the lateral method, —entering the knife three-quarters of an inch above the anus, and cutting obliquely downwards a little below the rectum and midway between that viscus and the tuberosity of the ischium. The incision is first carried through the skin and superficial fascia, after which a portion of the levator ani, the transversus perinei, the triangular ligament, the membranous urethra, the prostate gland, and the neck of the bladder are successively divided. But it is unnecessary to describe more minutely the various steps of an operation which has been performed in your presence four times already within the past three months.

After the bladder has been opened, the calculus is seized by means of forceps, and withdrawn only with a great deal of difficulty, for the stone is nearly an inch and a half in length.

Replacement of the rectum will not be undertaken at this time, because there will be considerable tenesmus for a few days after the extraction of the stone: the mucous membrane, however, will be protected from the urine with which it must come in contact, by means of ointment of the oxide of zinc.

To-day the reduction of this prolapsed rectum will be attempted, for the boy has been doing exceedingly well since I removed from his bladder, eleven days ago, the largest stone, weighing six and a half drachms; and there is not now that tendency to straining which generally exists for some time after the performance of lithotomy. The reduction is effected by gradually pushing up the bowel with the fingers, which have been previously oiled, in such a manner as to replace first that portion of the intestine which escaped last. By delicate manipulation the object is accomplished in this case without much difficulty, after which the action of the bowels will be controlled by opiates, and a compress held by a T-bandage applied under the perineum, to support the parts and guard against a reproduction of the displacement.

Here, walking before you, is the little patient who came to the clinic three weeks ago suffering from great prolapse of the rectum consequent upon the existence of vesical calculus. The perineal bandage applied at the time the bowel was replaced has been dispensed with for two days without any further protrusion, and now the boy, who for two years has been unable to stand or sit up, can walk about without inconvenience, so that to-day his mother will take him home cured.

TRANSLATIONS.

THE PATHOLOGY OF INFANTILE PARALYSIS.

IN the beginning of the year 1873 (Professor Roth, in *Bâle, Virchow's Archiv*) there died from diphtheria in the hospital at Bâle a boy who was suffering from spinal paralysis; and Professor Roth, through the kindness of one of his colleagues, had the opportunity of consulting the notes of the case and of making the autopsy.

The patient, a boy aged two years, was the son of a prostitute, and in the early part of the year 1872 could walk, but in February of that year, after an attack of some febrile affection, lost the power of locomotion. At his admission into the hospital in August there was incomplete paralysis of both lower extremities, which, however, was more complete upon the right side than upon the left. Under the application of electricity, the power of progression improved so much that the boy was at last able to walk, although there was frequently some dragging of the right foot. The diphtheritic deposit made its appearance upon the tonsils on the 21st of December, accompanied by an ill-smelling discharge from the nostrils, and was followed on the 27th by albumen in the urine, and œdema of the face and limbs. On the 4th of January, 1873, the boy died, eleven months after the appearance of the paralysis. The autopsy was made on the 5th, when the various organs of the body were found in the following condition. The limbs were very œdematous, and the various cavities of the body were dropsical. The tonsils were contracted by cicatrices, but there was no longer any diphtheritic deposit noticeable. The left ventricle of the heart was dilated, and there was a clot of the size of a cherry at its apex. The spleen was moderately enlarged, and the kidneys were larger than normal, and white and dense. The brain was not particularly altered, but the vessels of the pia mater were dilated and œdematous. When the dura mater of the cord was opened, a small quantity of fluid was discharged, and some adhesions of slight strength were found between the dura and pia mater, upon the posterior

part of the cord in the lumbar region. The larger blood-vessels of the same region were found much contorted and distended with blood. The anterior roots of the cauda equina were partly atrophied, were flattened, and appeared gray by transmitted light. When a transverse cut of the cord from the lumbar region was made, the gray substance of the anterior horns appeared of a dirty grayish-white color, indistinctly bounded towards the lateral fibre. In the dorsal cervical region the gray substance was of the normal hue and distinctly bounded; the posterior fibres, however, appeared more gray in color. Microscopic examinations were made of sections taken from various parts of the lumbar region of the cord, with the following results. In a transverse section made through the lower posterior fibres of the lumbar portion 23 mm. above the filum terminale, a very striking change in the anterior horn of the right side was found. Numerous nucleated cells were noticed, some of which were scattered through the tissues, while others were arranged in rows along the larger vessels, to the exterior coat of which they were attached. Between these cells there was a net-work of firm fibres analogous to fibres of connective tissue.

How far nerve-fibres were connected with this network was not determined. In this part of the section the multipolar cells had for the most part vanished; only after coloring with carmine and treating with Canada balsam could some solitary small ganglion-cells be noticed. Nerve-fibres containing marrow, which are usually seen running in the anterior horns both singly and in bundles, occurred only occasionally. These changes were noticed also in the base of the posterior horns, where some vessels covered with cells containing fatty nuclei could be seen running through the white substance towards the anterior notch and the anterior root. The bundle of axis-cylinders running from the gray substance towards the anterior root was contracted, and resembled dense fibres of connective tissue, while the region surrounding the central canal was normal. The anterior horn upon the left side appeared normal; the multipolar cells were numerous and of normal size.

For purposes of comparison, the anterior roots of the right and left sides were teased out, and upon examination the changes, as in the spinal cord, were found more pronounced upon the right side than upon the left. By the examination of sections of the cord at various positions, it was found that the evidences of inflammation extended through the entire length of the lumbar region, and that they manifested themselves in their greatest intensity in the middle and lower parts of that region, becoming gradually less marked above and below.

Professor Roth concludes from the post-mortem conditions that there existed eleven months before death, as the cause of the paralysis, an interstitial myelitis of the lumbar portion of the cord, situated especially in the gray substance of the anterior horn. The clinical observation that the paralysis was more marked upon the right side than upon the left agrees with the more marked evidences of inflammation found upon the right side.

The points at which the inflammatory products were found presented not only evidences of atrophy of nerve-fibres, but also an almost complete absence of large multipolar ganglion-cells. The consecutive atrophy of the anterior horn can be explained by the absence of nervous elements from the myelitic deposit, and this is more noticeable upon the right side than upon the left. From this it is certain that some cases of infantile paralysis are due to a myelitis of the anterior horns occurring at an early age as a consequence of acute disease. In other cases, however, the gray substance is not in-

volved, but the paralysis is due to a myelitis of the motor portion of the white substance of the spinal cord.

WILLIAM ASHBRIDGE, M.D.

GLYCOSURIA FROM THE ADMINISTRATION OF NITRO-BENZOLE.

DR. CARL ANTON EWALD, of Berlin (*Centralblatt f. die Med. Wissenschaft.*), has found that after subcutaneous injections of nitro-benzole in the guinea-pig, in quantities from 0.5 to 2 grammes, its urine upon being treated with animal charcoal affords a substance which possesses reducing powers and gives the characteristic reaction of sugar. This phenomenon is noticed as early as three hours after the experiment has been made, and continues until twenty hours have elapsed; and at the end of twenty-four to thirty-six hours traces of sugar have entirely vanished from the urine. The amount of sugar found is greatest four hours after the injection, when it reaches 1.9 per cent. But this may not be accurate, since a quantitative analysis of the urine was not made in all cases. In regard to the question of the influence of the splanchnic nerve upon the production of sugar in the urine, no conclusion was attained, because the animals which had been subjected to this operation died before the time requisite for the appearance of sugar had elapsed. In his experiments upon dogs he was unsuccessful in producing glycosuria by administering nitro-benzole hypodermically, but after giving it by the mouth sugar appeared in the urine in large quantities. If the different results from these experiments upon two classes of animals are constant, they may afford, upon the one hand, evidence of a characteristic difference in the action of the drug upon herbivora and carnivora, and, on the other, some clue as to the rationale of the production of sugar in the urine by the substance in question.

WILLIAM ASHBRIDGE, M.D.

POISONING BY CANTHARIDAL COLLODION.

DR. ERNST SCHWERIN, of Berlin, reports a case (*Berliner Klinische Wochenschrift*) of poisoning with cantharidal collodion. The patient, a woman aged twenty-three years, swallowed, through mistake, fifteen drops of the preparation. After about an hour had elapsed she was attacked with cramps in the lower part of the abdomen, for which, previously to sending for a physician, numerous household remedies were used. The doctor upon his arrival found the patient running about the room, with the arms crossed upon the abdomen, stopping after every few steps to void a few drops of urine, the passage of which was attended with intense pain. At times she fell into a species of catalepsy. The pulse was small and of moderate frequency. For some days albumen was found in the urine. Under treatment, she at the end of a few days was entirely recovered. It is interesting to notice that the sexual passion was not at all excited by the drug; and this goes to confirm the opinion of later observers, that the older physicians were mistaken in attributing aphrodisiac qualities to it.

WM. ASHBRIDGE, M.D.

ACTION OF ERGOT ON THE BLADDER (*Le Progrès Médical*, December 27, 1873).—Dr. Wernich affirms that the repletion of the bladder so often observed after the administration of ergot is due not only to a retention of the normal urine, but still more to a hypersecretion of the same fluid, provoked by the medicament.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, FEBRUARY 14, 1874.

EDITORIAL.

MEDICAL JURISPRUDENCE.

A FEW weeks since, a Mr. James A. Grant died suddenly at Greensburgh, New Jersey, under circumstances which were deemed suspicious, and a coroner's inquest was the result. The manner of conducting this inquest and the circumstances of the case seem to us so illustrative of the atrocious system of medical jurisprudence under which we live, liable at any time to be persecuted even to the death by the ignorance or recklessness of doctors, judges, and juries, that we have extracted the following summary of the testimony from the *Trenton Daily State Gazette* of January 10, 12, and 13:

"Dr. Abraham Livezey testified that he was a druggist and office-physician; remembered a little girl coming to his store with a paper on which was written, 'Rad. sarsaparilla, half a pound; hydriodot. potassæ, drachms four.' He weighed out the first article, took down the bottle containing the second and directed his clerk to weigh out the required amount, tasted it, remarked that it was 'salty,' and gave it to the girl. He had never sold any cyanide of potassium to any one, and kept the bottle containing it on the opposite side of the store from the one which held the iodide. All the packages he put up were marked. His clerk corroborated his testimony in every respect, and swore that he had read the words 'potassium iodide' on the bottle.

"Emma Grant testified that she had obtained the drugs as above described, but that only the package containing the sarsaparilla was marked, and that when Dr. Livezey tasted the medicine he said it was 'very bitter,' and that he 'pitied the person who had to take it.'

"Mrs. Grant gave an account of her husband's previous sickness, which was trifling. She had received the packages from her daughter, and about 7 A.M. on the following morning she mixed the white powder with twelve tablespoonfuls of water, and gave him two teaspoonfuls of the solution, followed by some tea to remove the taste, which, he said, was very bitter. Just as she turned away he threw himself down on his back, his face became extremely flushed, he turned and twisted as if in spasms, he gasped for breath, was entirely speechless, and died about eight o'clock.

"Dr. J. L. Bodine testified that he had made the post-mortem examination, and had found the lungs, liver, heart, spleen, brain, and kidneys healthy; that the stomach was ligated at both extremities and then removed from the body, and that on opening it there was an 'unmistakable smell of prussic acid or cyanide of potassium.' He was of the opinion that death had resulted from a poisonous dose of the latter drug.

"Drs. C. L. Minster, J. L. Taylor, and J. T. Corson were present at the autopsy, and corroborated the statements of the previous witness. They all agreed that the odor of the contents of the bottle from which the dose had been given, and that of the stomach, were identical.

"Edward Grant swore that he took a bottle from the room in which his brother died, and on the same morning gave it to a female friend, who put it in a closet, from which he took it in the following day and carried it to Dr. Isaac James, who testified that he had determined it was cyanide of potassium by 'the smell and the caustic effect on the skin.' He in his turn had kept the bottle until the next day, and had then sealed it and given it to the coroner.

"Dr. John W. Scudder swore that he had written the order as above, and had given verbal directions as to the mode of administration: when he reached the house the following morning the patient was dead. Mrs. Grant handed him a bottle, and said she was afraid she had given the wrong medicine; he tasted it, but detected nothing unusual in regard to bitterness; was present at the post-mortem, and agreed with Dr. Minster and the others.

"The jury, after deliberating for two hours, brought in the following verdict:

"We, the jury called to inquire into the cause of the death of James A. Grant, of the township of Ewing, in the county of Mercer, do find that the said James A. Grant came to his death on the sixth day of January, A.D. 1874, at his own residence in the township aforesaid; that he came to his death by having had administered to him a dose of cyanide of potassium.

"The jury aforesaid do further find that said medicine, taken as aforesaid, was sold by one Abraham Livezey, in Yardleyville, Pa., on Monday afternoon, the 5th day of January, A.D. 1874, on an order or memorandum written by Dr. John Scudder, and furnished for the use of the said deceased as iodide of potassium, but which, in the opinion of the jury, was cyanide of potassium, a poison, and that the putting up of said

medicine by Abraham Livezey aforesaid was an act of gross carelessness on the part of said Livezey.

"And the jury do further say that some stringent legislation is necessary in regard to the sale and compounding of poisonous drugs, by which the fatal mistakes so frequently occurring may be avoided, and the lives of the people better protected."

We might well draw a moral from the above sad story, as to the sins of apothecaries and the laxity of the law, but we forbear, and ask attention only to the medical testimony. Fortunately, we are spared this once the pitting of the so-called expert against expert; but as so much room has been left for this by the culpable laxity of the procedure, if the case ever comes into court, and Dr. Livezey finds it worth while to make a harder fight, we shall probably have another of these peculiarly American performances. In the name of decency, we ask, why was not a chemist employed to determine the presence or the absence of cyanide of potassium in the solution?—a question of a few moments' work. Instead of this obviously proper proceeding, although one doctor is represented as swearing that he tasted the deadly solution and could not perceive anything wrong, medical witnesses smell the corpse and smell the bottle, and parade their opinions that death was from prussic acid. These medical witnesses, it may be, were right in their opinions; but in cases of poison to opine when one can prove is simply to sin against society, to mock at justice, and to degrade, if it be possible, American medical jurisprudence.

It is an easy task to pull down, but often a very hard one to build up anew; and it is therefore with unfeigned pleasure that we have read an article by Dr. John Ordronaux (*American Journal of Insanity*, January, 1874) in which the learned doctor proposes a scheme that seems at first sight eminently practicable.

He very truly says that the basis of all the trouble is the refusal of the courts to accord any distinct legal status to experts, and shows, as we have previously insisted upon, that the real fault lies not with qualified experts, but with the courts and their utterly stupid and contradictory rulings. In a recent case tried at Annapolis, we saw a learned judge seriously decide that a man was not sick because he was going about, and, therefore, refuse to receive evidence proving that he was sick.

The fundamental idea of the plan proposed by Dr. Ordronaux is to remove the experts from the sphere of the witness and to give them a quasi-judicial authority. The matters in question are to be submitted for trial to a commission composed

of three experts (one appointed by the court and one by each of the contestants), precisely as issues of fact are sent by courts of equity to be tried before masters in chancery. This trial is to be preliminary to that before the court, in order to save the time of the latter.

This plan is very probably the best for cases of lunacy, and, it may be, in many other instances. But in poisoning-cases it may happen that the facts upon which judgment is to be formed are so different as told by the opposing witnesses as to require two distinct opinions; and it may be also that the facts are brought out only upon the cross-examination of the witnesses at the trial. For these reasons, any opinion framed before the trial would evidently be premature; so that we conceive that the facts should be submitted to the commission as fast as developed during the trial,—the opinion to be delivered at the close, after the evidence is all in. It would be a very rare case that would require more than a night for the commission to frame its opinion under the above circumstances.

IF nothing that a medical journal can say can affect our advertising hospital brethren,—if Siamese twins are to be made the platform for advertising only less monstrous than the subject which affords its pretext,—if the itch for notoriety which afflicts so many of the profession can't be cured by the counsel of brethren, we trust the following, taken from the *Galaxy*, a secular magazine, may reach at least one case:

"A social or political committee embraces W. M. Evarts, D. Webster, C. Cushing, and so on; but always G. Washington Squills, M.D., or, more modestly, Dr. G. W. Squills. For example, we see in the newspapers a public notice like this:

"The undersigned beg their fellow-citizens to unite in honoring with fit ceremonies the approaching anniversary of the birthday of Washington.

C. Cushing,	David D. Porter,
Dr. Timothy Tubbs,	W. T. Sherman,
Henry Ward Beecher,	T. W. H. Gallipot, <i>M.D.</i>
Gideon Welles,	Charles Sumner.'

"Are not such shows of titles a trifle ridiculous? Mr. Beecher does not write his 'Rev.' before his name, nor does Charles Sumner tail his LL.D. after it: it is only Tommy Gallipot that stickles for these things. I should think a doctor would feel cheap in thus advertising himself in an affair that has nothing to do with drugs, as in some matter of a committee upon a charity, or a flower-show, or a Christmas ball, or a testimonial to the genius of a nigger minstrel, or the celebration of the Fourth of July. But no; the smallest fry of a physician displays his titular grandeur alike when signing

his name to a communication on politics in the morning newspapers, or when leaving a visiting-card at his friend's in an unprofessional call."—*Galaxy for January.*

OWING to a mistake in a hastily-written letter, we were misled in regard to our figures as to the amount appropriated annually by Congress for the Army Medical Library. The usual appropriation has been five, not fifty, thousand dollars, and it is that sum which was asked for this year by those in charge of the library. On February 5 the appropriation asked for (five thousand dollars Army Medical Library—five thousand dollars Army Medical Museum) was restored to the bill in the House of Representatives.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, JANUARY 14, 1874.

DR. JOHN SWINBURNE in the chair.

BY resolution, the President appointed a committee of Drs. Blatner, Freeman, and Bigelow to draft resolutions in reference to the death of Dr. J. H. Lasher; and a committee of Drs. James McNaughton, Boyd, and Quackenbush, to take similar action in reference to the death of Drs. Peter Van Buren and John F. Townsend.

DEATH FROM CALCULUS IN THE URETHRA.

DR. E. R. HUN reported the following interesting case:

W. J., æt. 53, came January 26, 1873, complaining of difficulty and pain in passing water. He stated that while in the British army, twenty-four years ago, he contracted gonorrhœa, for which he was treated by astringent injections, which put an end to the discharge in a few days. For the next ten years he had no further trouble, until he suddenly was unable to pass water. The catheter was resorted to effectually, and for some time he had no further symptoms. About six years ago he observed that the stream of urine was becoming smaller, and that it took him a long time to empty the bladder; and said that a few years ago, after retaining his urine for some time and making forcible effort to expel it, he passed two or three small, gritty particles which occasioned very considerable pain. During the past three years he has never been able to pass water freely, and has several times suffered from retention, which has been relieved by warm baths and various internal remedies advised by friends.

His urine now was expelled drop by drop, and his underclothes were constantly wet with it. He was emaciated, and too feeble to do ordinary work. He did not rest well at night, and had but little appetite.

Upon attempting to introduce a silver catheter, it was arrested about an inch from the meatus by a firm, unyielding stricture. A No. 2 olive-pointed bougie could be passed through this stricture, but encountered another about two inches farther back, through which it was passed with difficulty, although stiffened by the introduction of a wire stilet. A third stricture was met with in the membranous portion of the urethra, after passing which, the instrument entered the bladder. Upon removing the bougie and examining it, he was

surprised to find it cut and scratched on its exterior as if it had been drawn on some hard and jagged body. Dr. Hun then felt along the urethra, and found a calculous mass lying between the second and third stricture which could be pushed up and down the urethra. He endeavored to dilate the anterior stricture by graduated bougies, but it was so firm and unyielding that he made no headway.

A short time after he first saw the patient, the State Society met in Albany, and Dr. Otis, of New York, exhibited his new urethrotome, which he (Dr. Hun) thought would be just the instrument for such a case as the one above described, and therefore asked him to meet the patient at his office, which he did, and tried to introduce the instrument. The stricture, however, would not admit it, and Dr. Otis then tried to enlarge the passage with a Maeraman's urethrotome. After considerable difficulty, he succeeded in passing through the largest-sized blade of Maeraman's, and followed it with his own instrument, but not without using force, so dense and unyielding were the fibrinous bands forming the two anterior strictures. The doctor then, by means of the screw in the handle, opened the blades of his instrument so as to dilate the strictures preparatory to dividing them, but after a few turns of the screw the blades became clogged with the calculous material contained in the urethra, and he could neither open nor shut it. He managed to withdraw it with great difficulty, and the pain occasioned by the process was so great that the patient refused to allow anything more to be done, and insisted upon going home. He was seen the next morning by Dr. Hun, who found the penis much swollen. He had passed only a few drops of urine, and the bladder was distended. He was advised to have the calculus removed by external urethrotomy, and allow exit to the urine, but obstinately refused. He persisted in his refusal for four days, although in the mean time he suffered great pain, and the urine only came away drop by drop.

On the fifth day after Dr. Otis had seen him, he consented to go to St. Peter's Hospital, when he was at once etherized, and Dr. Swinburne opened the urethra just in front of the posterior stricture, when the calculus, one inch in length, and sufficiently large to fill the urethra, besides small pieces of gravel, was removed. The gum-elastic catheter was then passed into the bladder, when a large quantity of offensive urine passed off. The whole penis was sloughing from urinary infiltration; the scrotum and several points in the groin were incised, and gave vent to purulent matter having a strong urinary odor. The patient gradually sank, and died forty-eight hours after the operation.

No autopsy could be obtained.

Dr. Hun remarked that from the size and shape of the calculus it must have been in the urethra for a long time, and that it was an interesting point to determine whether it originally formed in the dilated portion of the urethra between the two strictures, or whether it passed from the bladder as a small particle of gravel and afterwards increased in size by the deposit of phosphatic matter from the urine, which was constantly retained in the pouch in which it was found. The doctor favored the latter opinion, from the fact that particles of gravel were found with it. He remarked that, from his experience in this case, he should not attempt to dilate the stricture, but would perform at once external urethrotomy, in similar cases.

DR. HENRY MARCH mentioned five interesting cases among those having occurred in the practice of his father, Dr. Alden March.

OLD EYES MADE NEW—INTRAOCULAR RUPTURE.

DR. C. A. ROBERTSON addressed the Society as follows:—I present for your observation a picture cut from

an advertisement representing a cup about to be applied over the eye of a person by the hand, which holds an elastic india-rubber ball. Below you may read the glowing exclamation,—

"RESTORE YOUR SIGHT! Spectacles and surgical operations rendered useless! The inestimable blessing of sight is rendered perpetual by the use of the new patent improved eye-cups."

In displayed type it is announced that—

"Mrs. Rev. Henry Ward Beecher, after using the ivory eye-cups, ordered a pair for the wife of Rev. Charles Beecher, of Georgetown, Massachusetts."

I deem it a duty to utter a warning against the employment of this cupping apparatus, as not only a sheer imposition, since it is false in principle, but as also exceedingly dangerous to the well-being of the eye. It is an old contrivance for the purpose of gain, and is palmed off regardless of the consequences that dupes may suffer. A few years ago an advertisement appeared in the journals to this effect:

"Old Eyes Made New! Send for a pamphlet, price ten cents." The ten cents would bring back a pamphlet containing a description of the cups, stating how the eye flattened by age could be restored to its pristine state, and giving numerous testimonials of their efficacy. Of course these were all false. I was told that these cups were made at a factory at or near Hudson, New York. The pair which I saw were turned out of wood; instead of the single cup and clumsy hollow ball to exhaust the air, represented in our picture, which can cup only one eye at a time, there were two little wooden cups, each furnished with a small piece of india-rubber tubing that connected in a Y-shape with a larger tube. The rejuvenator of his eye was required to place the main tube in his mouth, apply the cups over his senile eyes, and then suck away.

It is hardly necessary in this Society to dwell on the dangerous congestion of the delicate structures of the eye inevitably incident to this dry-cupping operation; to the liability of rupturing delicate blood-vessels within the eyeball, or to mention (all risk being set aside from consideration) that the convexity of the cornea which could be produced must inevitably be very transient, and the reaction to its former shape very rapid. You remember the old Roman proverb, "Drive out nature with a fork, and she will come running back." The idea that the eyeball possesses such plasticity that it could be altered in form by external force being applied, was conceived by Benjamin Franklin. He advised pressure with the thumb and fingers around the eyeball, so as to force the flattened front of the eye or cornea into a greater degree of convexity, and by consequence increase its refractive power and obviate the necessity of spectacles. There were, however, two serious errors in the premises from which Franklin reasoned. One error was the intenable assumption that the cornea can be moulded into convexity so as practically to compensate presbyopia or old-sight; the other was the notion that the sight fails in advancing years from a flattening of the eye.

This latter notion still remains in the popular mind, and it is also generally supposed that near-sightedness is the opposite of old-sight (sometimes called far-sight), and, being due to excess of convexity, that the defect of near-sight will diminish as age advances. Although occupying still a place in text-books of natural philosophy, these notions are to-day demonstrated erroneous.

It has been proved by actual measurement that the cause of near-sightedness is the too great length of the eye from front to back, and a consequent formation of the visual image is front of the retina instead of upon it. In order to throw the image farther back, a concave glass to divide the rays of light is required. This defect is therefore structural or anatomical. Not so, how-

ever, in presbyopia. The sight of those who require spectacles for reading or sewing does not fail for perceiving distant objects. It is only in looking at small objects near by that the necessity for glasses is felt. If the small object is near by, the object refuses to focus or accommodate so as to make an image on the retina as in youth. If it is removed to a greater distance, a very small object will not form in the eye a sufficiently large image to excite visual sensibility. The long-mooted question as to where the power of focusing or accommodating for different distances is situated has been incontrovertibly settled, and it has been conclusively shown that varying degrees of convexity of the crystalline lens, and especially of its anterior face, determine the accommodation.

Helmholtz, by a delicate instrument, measured the image of a candle-light reflected on the front surface of the lens, and found it greater when the eye was regarding distant objects than when regarding near ones. As the size of an image made by a convex mirror is in inverse ratio to the degree of curvature, it follows from the experiment of Helmholtz that the anterior reflecting surface of the crystalline lens is less convex in regarding distant objects than when accommodated for near objects. Helmholtz also found that no change took place in the size of the conical image reflected from the cornea while vision was accommodated, whether for a near or a distant point. When the lens is wanting, no accommodation exists. It has been determined by careful observation of many thousand cases that the power of accommodating for a near point sensibly diminishes from the age of ten years, as the lens becomes firmer, until at about the age of forty it cannot achieve sufficient convexity for accurate definition of fine objects close at hand, and the necessity arises for augmenting the refraction artificially,—in other words, for using convex glasses, the ordinary spectacles of elderly persons.

From these considerations it is clear how radically erroneous is the theory that presbyopia may be cured by modifying the convexity of the eye, or cornea rather; and it is also clear that failing sight is owing to a physiological change or hardening of the lens, which begins at an early age.

I have said that these eye-cups are dangerous, and that warning should be given against their employment. In proof of this I will relate a single case.

Mrs. B., the wife of a wealthy gentleman in a neighboring city, found her sight failing: she did not like to resort to the use of glasses, and, having seen the eye-cups advertised as a sure cure, she tried them. After a short time, the sight of one eye was lost. She therefore consulted an oculist of high repute in another city, who examined her eye with lenses and artificial light and stated to her that she had a cataract.

On her return home I chanced to spend a Sunday with friends in the city where she resided, and her husband requested me to ride out to his residence, and, if possible, to cheer her up. Assuming the diagnosis given as a foregone conclusion, I was a good deal perplexed as to what I should say to do so; but, after having engaged in conversation with her, I requested her to give me the history of her case. She stated that her sight was good until within a few weeks, except that she felt the need of glasses; and she went on to speak of using the eye-cups. One day, she said, a black spot appeared before the right eye, and almost immediately it seemed to shoot out processes like a spider's legs, and her sight was soon gone. This history the gentleman alluded to had not sought before committing himself to the diagnosis of cataract.

I was glad to find in her account of the manner of losing her sight some ground for encouraging and cheering her, without even troubling her to submit to

an examination of the eye, which she seemed to dread lest it should only confirm the opinion already received. I assured her that I was confident that my friend had made a mistake, and that she had no cataract; for her history of the case, and the manner of invasion of her blindness, negatived the probability of it. I gave my opinion that by the use of the dangerous eye-cups she had ruptured a small blood-vessel, and that the appearance of the spider-like spot was due to intraocular hemorrhage, which I believed would be absorbed and her sight restored. I advised her to keep quiet in a shaded apartment, give her eyes absolute functional rest, and throw her eye-cups into the fire. I had the gratification to learn by letter from her husband, within three or four weeks after, that her sight had completely returned.

I regard this as a fortunate escape for her, for it is not always that the effects of intraocular hemorrhage disappear so completely.

CASE OF PNEUMONIA.

Dr. JAMES P. BOYD, Jr., reported the following case: A few months ago a patient was admitted at St. Peter's Hospital, with the following history: Age 26; Irish; laborer; he stated that a few days before coming to the hospital he had a chill, followed by feverishness and loss of appetite. His previous health had been good. On the evening of admission the temperature was 102°, pulse accelerated, respiration normal, and otherwise nothing of interest. A laxative was prescribed, and the ordinary diaphoretic. The second night after admission he became delirious, and was with difficulty kept in his bed. He told the attendants at this time that "his bladder had burst, and that he could not pass his water." Previous to this he had passed his water regularly and without difficulty. A catheter was introduced by the house-physician, and a moderate quantity of highly-colored urine drawn off. Nothing abnormal was discovered in the region of the bladder and urethra. Urine found to contain urates in abundance. On the following morning temperature 104°, pulse 90. His face was now somewhat flushed; pupils normal; delirium continued during the day, but was of a good-natured character. The patient's gait on attempting to walk was unsteady. On the evening of this day the temperature was 105°, pulse was 100. The fourth day after admission the temperature in the morning was 103°; evening, 105°. Fifth day, temperature, morning, 103°; evening, 103.5°. Sixth day, temperature, 103°; evening, 105°. Seventh day, morning, 103°; evening, 104°. Eighth day, morning temperature 104°; evening, 105°. Up to this date the urine had been drawn off regularly; the delirium had continued, although not so marked as at first; the respiration had been easy; the patient had complained of no pain. On entering the ward at this date I observed for the first time that the breathing was hurried, and that the lips were slightly cyanotic. He did not cough. On examining the chest I found slight dulness over lower lobe of right lung, and not very marked dulness over left lung. Crepitant râles were heard on the right side of chest; the chlorides were found to be diminished in quantity in the urine. Ninth day, temperature, morning, 104°; evening, 105°. There was increased dulness over the lower lobes of both lungs; fine crepitant râles over both sides of chest. A herpetic eruption on the lips; increased cyanosis; cough for the first time. Tenth day, temperature, morning, 105°; evening, 105°. Complete dulness over lower two-thirds of both lungs; bronchial breathing; bronchophony; increased vocal fremitus. Twelfth day, temperature, morning, 106°; evening, 107°: this was the highest point reached in the disease. The characteristic rusty sputa of pneumonia were present. From this date the temperature fell, and slowly returned to the normal

standard of health; the bronchial breathing and bronchophony gave place to the râle redux; the dulness gradually disappeared, and the lungs once more were in normal condition. The patient was in the hospital six weeks, and confined to bed four weeks; he was then discharged, cured.

The treatment consisted in the use of the oil-silk jacket, quinine, carb. ammonia, and nourishing diet.

The points of interest in connection with the case are, first, the length of time existing between the chill and first symptoms of trouble in the respiratory apparatus; second, the slowness of the pulse when compared with the high temperature of the disease, to which the German authors call attention; third, the absence of all pain and cough until after the disease had been fully established; fourth, the well-marked stage of delirium.

FALLOPIAN SALPINGITIS.

Dr. JAMES P. BOYD, Jr., also reported the following case, and remarked that the specimen presented was taken from a woman aged 25; married; never had children; had lived fast; died in a fit of intoxication while suffering from Bright's disease. The liver was fatty, and weighed seven pounds; osseous deposits on mitral and aortic valves; membranes of brain thickened and opaque; kidneys enlarged and fatty; mucous membrane of stomach dark red, and congested; evidences of chronic inflammation. External genital organs perfect. Uterus normal in size; virgin cervix; mucous membrane of cervix and fundus in a state of chronic inflammation, and covered with a thick, tenacious substance which on examination is made up of pus-corpuscles, fat, and débris of epithelium. Very slight and beginning cell-proliferations in tissue adjacent to mucous membrane. The Fallopian tubes admit a very fine probe for a distance of about three-fourths of an inch, beyond which point they are impervious. The tubes for the distance of three-fourths of an inch from uterus are straight, and under the microscope present nothing special. The arborescent arrangement of folds of mucous membrane remains, but the epithelium is destroyed, and pus-corpuscles are numerous. About one inch from uterine mouth both tubes are evidently dilated, and terminate in fluid sacs over the ovaries. The fimbriated extremities cannot be recognized. The abdominal extremities of both tubes are bound by firm adhesions to ovaries. The mucous membrane of the dilated tubes is replaced by a smooth, shining membrane consisting mainly of cellular tissue, and covered by some cells of flat form. The remaining coats consist mainly of cellular tissue. Contents of each tube weigh two ounces, and consist of a greenish, gelatinous substance, which, on examination, is found to contain pus, fat, and granular bodies. Ovaries are about normal in size, and on section show numerous small cysts. Both ovaries firmly bound to the tubes.

REVIEWS AND BOOK NOTICES.

STATEMENT OF THE TRUSTEES OF THE PENNSYLVANIA STATE LUNATIC HOSPITAL IN REGARD TO CERTAIN CHARGES OF THE BOARD OF PUBLIC CHARITIES OF PENNSYLVANIA. Harrisburg, 1874.

It is an old saw, that one story is good until another is told, and the present seems an illustration of the wisdom of the saying. In a recent editorial founded upon the "Plea" of the State Board of Public Charities, we cast reflections upon the management of the Harrisburg Asylum, at least so far as concerns the reception of patients. Frightful evil and abuse certainly exist somewhere, and we somewhat hastily, perhaps, as-

sumed that the State Board were correct in laying at least a part of the abuse at the door of our State Asylum. The present pamphlet denies this, setting forth and seemingly establishing the following propositions:

"1. That the Trustees at all times, until the wards of the hospital became crowded, received all patients who were brought to the Hospital.

"2. That when the wards of the Hospital became crowded, the Directors of the Poor of the counties, and the Overseers of the Poor of the townships, were distinctly and uniformly told that any recent cases they might have in charge would be admitted at any time without waiting for the formality of writing, but that, as the law distinctly gave the preference to recent cases, cases of many years' standing could not be received.

"3. That patients have not been sent away by the Trustees 'if not speedily curable,' but, except in certain cases to be mentioned afterwards, were retained as long as the Directors or Overseers could be induced to leave them.

"4. That preference has never been given to paying patients; but they were received with the distinct understanding, expressed in words in the bonds signed by the friends who are responsible for their expenses, that they were to be removed whenever required to do so by the Superintendent.

"5. That of the class of paying patients, a very limited number only could be classed under the term rich; but the great majority either had no means of their own and had to be supported by their friends, or had limited incomes which allowed them only to pay the lowest rate of board, and clothe them, and many could not pay more than the amount charged to the public authorities.

"6. That the Trustees of this Hospital have, year after year, in their published reports, urged the great and pressing necessity of more hospital accommodation for the insane poor of Pennsylvania.

"7. That persons acquitted of crime committed while laboring under mental disorder, and consequently irresponsible, have not been refused admission into the hospital until the wards became crowded, and then only on the provision of the law in regard to recent cases having the preference.

"8. That in the first report of the hospital, as in a great many subsequent reports, the Trustees have urged the establishment of a separate institution for insane criminals, meaning by that term a peculiarly dangerous class of criminals in the jails and penitentiaries; and also that they presented to the Legislature of 1863 a memorial praying for the establishment of such an institution."

We confess this controversy is getting beyond us; and an elaborate investigation of the whole matter is needed,—not to discover who is to blame, for that to the public is of trifling importance, but to get at the best method of reform. The subject is now before the legislature, and we trust that august and most honorable body will give it their best attention, and, having heard all sides and received the views of all who are worthy to be listened to, will come to a wise and righteous decision.

A PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. By J. FORSYTH MEIGS, M.D., and WILLIAM PEPPER, M.D.

Most good scientific books, like human beings, improve for a time after they come upon the stage of action, but sooner or later suffer from the decrepitude of old age and go halting and limping out of sight. The treatise before us is quite an old one, but, owing to the wisdom of its originally sole author in joining to himself some four years ago an associate at that time young in years but rich in lore, and also in leisure,

the book renewed its youth, and started on a fresh career of usefulness. The popularity we predicted for it then has been enjoyed, and in the presence of this verdict we merely say, amen. In the present edition, the articles on diseases of the heart, on progressive muscular sclerosis, on the treatment of scarlet fever and of measles, on variola, and on vaccine disease have been rewritten, and chapters upon pulmonary emphysema, pneumothorax, affections of the tonsils, retro-pharyngeal abscess, malarial fevers, and scrofula have been added. Rendered thus more perfect and exhaustive, the book is still more worthy than before to rank as the most complete treatise upon the subject in the language.

A UNIVERSAL FORMULARY. By R. EGGLEFIELD GRIFFITH. Third Edition; carefully revised and much enlarged by JOHN M. MAISCH. Philadelphia, H. C. Lea, 1874.

This new edition of a well-known book reminds us of the woman in the Scriptures who had suffered many things of many physicians,—each issue of the volume having been superintended by a new editor. The merits and demerits of the work are too well known to need comment from us, and the name of Professor Maisch is sufficient guarantee that so far as concerns pharmacy the edition is well up to date. In looking over that portion of the book which deals with poisoning, we find much that has a "very ancient and fish-like smell."

CLINICAL RESEARCHES IN ELECTRO-SURGERY. By A. D. ROCKWELL, A.M., M.D., and GEORGE M. BEARD, A.M., M.D. New York, William Wood & Co., 1873.

This little brochure of seventy-one pages is chiefly composed of reports of cases in which electrolysis or the galvanic cautery was employed. By surgeons it will be read with pleasure.

GLEANINGS FROM OUR EXCHANGES.

EXAMINATION OF THE BLOOD-GLOBULES IN LEAD-POISONING.—M. Malassez made known to the French Biological Society (December 6, 1873) his conclusions relative to the alterations which take place both in the number and in the size of the red blood-globules, and reported his observations on eleven cases of lead-poisoning.

The normal mean number of red globules, 4,500,000 per cubic millimetre of blood, is reduced to 3,700,000 or to 3,200,000 during the presence of the acute symptoms.

The deficiency in the number of globules is more or less marked, according as the workmen are in a greater or less degree exposed to the lead-dust while practising their trade. In those poisoned the red globules are not only less in number, but they are also increased in size: they present in fact a diameter of the nine or ten thousandth part of a millimetre, seven and eight being the normal average. This increase in the dimensions of each globule is not compensated by the diminution in the number, and renders the circulation difficult in the fine capillaries.

M. Bouchard has estimated the *urochrome* of the urine of those poisoned by lead, and has proved that this coloring-matter is increased in quantity when the acute manifestations, arthritis, colic, and head-symptoms, are present. There must be, therefore, considerable activity in the destruction of the red globules during the acute period of the disease, which shows that hæmatic icterus comes on when the kidneys are not able to eliminate the *urochrome* resulting from this destruction.—*Le Mouvement Médical*.

THE GLANDS OF THE STOMACH.—M. Lépine made the following communication to the Biological Society of Paris at the session of December 6, 1873: The conclusion which M. A. Bernard has drawn from his numerous experiments is that the glands of the stomach are not acid, and that it is only the surface of the mucous membrane which presents reactions of this nature; but some German authors, Heidenheim among others, have made researches upon this subject which have led to contrary results. M. Lépine, however, has re-performed a series of experiments, the results of which verify the conclusions of Bernard. Taking the mucous membrane of the stomachs of dogs killed by section of the medulla oblongata, he has observed that this membrane becomes stained in patches when a solution of ferrocyanide of potassium is applied to one part and some sulphate of the peroxide of iron to another. Prussian blue is formed, but only on the surface of the mucous membrane, and not in the glandular cul-de-sacs.—*Le Mouvement Médical*.

INTRA-VEIN INJECTION OF WATER IN A DOG—DEATH.—M. Laborde presented, at the same session of the Biological Society of Paris, the viscera of a dog into whose veins he had injected, in one hour, a litre and a half of tepid water. Death followed quickly. He found apoplectic lesions and great congestion of the lungs, ecchymosis in the interior of the walls of the left side of the heart, and intense hyperæmia, with tumefaction and a violet coloration of the mucous membrane of the stomach and intestines. M. Laborde reports that during the previous week the dog had taken each day one gramme of sulphocyanide of potassium.

The author has yet to determine the cause of the above alterations.—*Le Mouvement Médical*.

THE INTRA-UTERINE STEM (*The Lancet*, December 27, 1873).—Dr. Routh recommends the use of the intra-uterine stem—1. In cases of *membranous cervix*. 2. In cases of *amenorrhœa* not due to anæmia, but to a stoppage from some other accidental cause. 3. In cases of *dysmenorrhœa*, whether due to mechanical obstruction or to neuralgic trouble. 4. In cases of *uterine flexion*. He believes the necessary conditions in the formation of an intra-uterine stem to be that—1. They should allow an omnilateral movement of the uterus. 2. They should not be longer than two inches, save in exceptional cases, in order that they may not touch the fundus uteri. 3. They should be bicornate superiorly, so as to be retained in utero. 4. Their diameters should not be too small. 5. They should be light, and not easily corroded.

FORMULA FOR INTERTRIGO.—M. Legal recommends the use of subnitrate of bismuth in eruptions caused by scratching, induced in turn by the itching of intertrigo. Glycerin is employed as an excipient, because it does not become rancid, and the tincture of cochineal to give a color. R Subnitrate of bismuth, glycerin, of each eight grammes; tincture of cochineal, twenty drops.—*Boston Medical and Surgical Journal*.

ARTIFICIAL PRODUCTION OF RICKETS AND MOLLITIES OSSIIUM.—C. Heitzman has shown by experiment that mollities ossium and rickets are identical processes, which may be produced artificially in animals by giving them lactic acid. In carnivora, the continued use of lactic acid causes first rickets and then mollities ossium, while in herbivora it produces mollities at once, without rickets.—*London Medical Record*.

FRACTURE OF THE CORACOID PROCESS OF THE SCAPULA, BY MUSCULAR ACTION (*The Lancet*, November 22, 1873).—A miner, æt. 57, slipped on a bank in the act of passing through a wire fence, and in falling his

left arm caught in one of the wires. He instantly felt a severe pain in the fingers, followed by loss of power in the arm and inability to raise the elbow from the side. On examination, it was found that the coracoid process of the left scapula was fractured and drawn downwards. This was treated in the usual way, and resulted in a cure in about two months.

TREATMENT OF TYPHOID FEVER.—The Paris correspondent of the *British Medical Journal* reports a lecture of M. Béhier's upon the diagnosis and treatment of typhoid fever. He urges particularly the use of the thermometer, and asserts that with this instrument alone he can diagnose typhoid fever from any other affection. His treatment consists of hydrotherapy and alcohol, and is, he says, refrigerant in the true sense of the word. He prescribes three baths a day, at a temperature of 68° Fahr., the patient to remain in for fifteen or twenty minutes at a time.

Intestinal perforations, old age, pregnancy, and menstruation, he considers to be contra-indications to the employment of the cold bath, but in every other case he has recourse to this heroic remedy, even in pulmonary complications; and, though he does not look upon it as a specific, he has found it to be almost infallible. As to the use of alcohol, whether as a food or medicine, he believes it to be invaluable in typhoid fever and in all inflammatory affections whether acute or chronic. In typhoid fever he prescribes eighty grammes (about two and a half ounces) of brandy daily, with an equal quantity of water, administered in divided doses.

Professor Sée is not so enthusiastic as to the curative powers of cold baths and alcohol in typhoid fever. He contents himself with an occasional bath or sponging the body with vinegar and water, and, instead of brandy, he prescribes wine and water, administering at the same time small and repeated doses of quinia.

LIGATURE OF THE DUCTUS CHOLEDOCHUS (*Le Progrès Médical*, December 20, 1873).—M. Odige tied the ductus communis choledochus in a dog, which survived the operation for fifteen days. A very few hours after the ligation he was able to recognize the presence of bile in the urine, thus apparently invalidating the statement of Frerichs, that coloring-matters could not be found in the renal secretion for thirty or forty hours. He believes the latter author could not have tied all the biliary ducts. He found that no discoloration of the skin was manifest until later.

GALVANIZATION OF THE SYMPATHETICS (*Le Progrès Médical*, December 27, 1873).—M. Onimus has found, by ophthalmoscopic examination, that the vessels around the pupil dilate during electrization of the superior cervical ganglia, and the circulation becomes more active when the electrodes are placed on the skin about on the level of the latter. He has applied this observation therapeutically, and in three advanced cases of atrophy of the optic nerve he has galvanized these ganglia. Although the treatment did not produce a complete cure, he obtained a marked amelioration, probably attributable to the influence of the electrization upon the activity of the retinal circulation.

ALLEGED CURE OF LEPROSY.—The *Friend of India* reports that the Madras surgeon in medical charge of the penal settlement at Fort Blair believes he has made a valuable discovery in the cure of leprosy. He is of opinion that leprosy can be cured by the oil of the gurjun-tree. Every leper in the settlement is, it is stated, being cured fast of this loathsome disease. In no case has there been the slightest failure, and the disease has been arrested at every stage.—*Druggist's Circular*.

MISCELLANY.

HORNET-STING.—In addition to the local irritation produced by the stings of bees, hornets, and wasps, severe and even fatal results are sometimes known to ensue. In a case observed by Dr. R. M. Cooper, a lady, having accidentally approached a hornets' nest, was stung six times upon the crown of the head, through a sun-bonnet, and four times on the back of the neck. She suffered severely at the time from the stings, and was found by the physician, an hour afterwards, in a cold, collapsed state, with pulse thread-like and almost imperceptible. Though her condition appeared at first to be a critical one, under the influence of active stimulants she eventually rallied. Upon the following day an intense itching was experienced over her whole body, which was found to be the seat of an erythematous eruption. This eruption disappeared at the end of thirty-six hours.—*Transactions of New Jersey Medical Society.*

REVOLT OF LUNATICS.—A revolt occurred a few days ago in the lunatic-asylum of St. Andrew's, near St. Petersburg. While the keepers were at dinner the patients burst into a room where some arms were stored, and, having distributed them, prepared for resistance. The wardens endeavored to calm them by argument, but ineffectually, and some of the keepers, having approached too near, were seized and attacked with sword-cuts. Five were killed and two seriously wounded. Recourse was then had to famine; but forty-eight hours' fast was endured before the madmen laid down their arms. Six of the most furious have been placed in separate cells, with strait waistcoats on them.—*Recent paper.*

"THE noisy and pretentious form of medical superstition which was introduced by Hahnemann is passing to decay through the customary intermediate stage of a dying delusion,—the stage of fraud."—*British Medical Journal.*

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—I have been a reader of the *Times* for over a year, now, and can say for it that it is the best medical journal published, as I have been a reader of almost all American, also some English and German journals, but none come up to the *Times* for variety of medical news. The report of thirty cases of chorea in the number for January 3, 1874, made me think of reporting ten cases that I have treated during fifteen years. Of these, eight were females, and two males; the oldest 14, and the youngest 7. Most of them were treated with strychnia and iron, and some with arsenic and iron; zinc I have never used; in one case ether spray to the spine acted like a charm. This was a bad case, and in two weeks after using the spray all movements and jerking of the limbs had ended, although it had lasted for more than six months before treatment. All ten cases were cured, and are now all hale and in good health.

Carbolic acid I have used for the last five years in tinea sycosis and found it efficient. I have under treatment now two cases; one is well, the other is undergoing a treatment of hyd. chlor. corros. and mur. ammoniac in water, after first removing the hair. I have been treating typhoid fever after the mode of Prof. Binz, by giving large doses of quinia and whisky, and also other stimulants, with good success. Of five cases thus treated this winter, all recovered. The ages of the five cases were from 17 to 14 years;

the duration of the fever was from sixteen to twenty-one days. All of the cases are now in a better state of health than before the disease.

In one case of gunshot wound of the arm, some years ago, I gave brandy, one quart a day, for at least four weeks, with good diet, and if it had not been for the alcohol the patient would have died; for so soon as the brandy was omitted for a few hours he began to fail, and the temperature began to rise from 97° or 98° to 100° and 103°.

I have the honor to remain truly yours,

C. H. SMITH.

KENTON, OHIO, January 14, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I have just read with great interest Dr. Clarke's little book on "Sex in Education;" and, while fully appreciating the value and excellence of the work, I feel constrained to protest against its extreme "plainness of speech." Dr. Clarke could have made himself equally well understood without being so coarse as he is in many instances.

I can hardly imagine Dr. Clarke's talking to the New England Women's Club about "hermaphroditic spinsterism" or the "castration of femininity;" by the by, if he is writing English, why doesn't he say the "spaying of femininity"? The introduction of the subject of eunuchs is quite unnecessary, having, it seems to me, no bearing on the question. Moreover, Dr. Clarke is not correct when he says, "Except the Secretary of the Treasury in the Cabinet of Candace, Queen of Ethiopia, who was baptized while journeying, by Philip the deacon, none of that class (eunuchs) have made any impression in the world's life that history has recorded." The *Encyclopædia Britannica*, in the article on Eunuchs, says, "The vulgar notion that eunuchs are necessarily deficient in courage and in intellectual vigor is amply refuted by history. Narses, the famous general under Justinian, was an Eunuch. Such, also, was Herminias, Governor of Atarimea, in Mysia, to whose manes the great Aristotle offered sacrifices." Origen, the celebrated Christian teacher and scholar, who was born in the second century, castrated himself early in life. In a little volume called "Eunuchism Displayed," published in London in 1740, the writer relates numerous other instances of the capacity of eunuchs and their power in the courts of the Eastern kings and later Roman emperors; but it is hardly worth while to repeat them, as many are well known.

Yours, truly,

W.

COMPANION TO THE FAMILY MEDICINE-CHEST.

Moral.—Send for the doctor.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM FEBRUARY 3, 1874, TO FEBRUARY 9, 1874, INCLUSIVE.

WIRTZ, H. R., SURGEON.—Died at San Francisco, California, on January 24, 1874.

PHILADELPHIA MEDICAL TIMES.

THURSDAY, FEBRUARY 19, 1874.

PHONOGRAPHIC REPORT.

THE SIAMESE TWINS AT THE COLLEGE OF PHYSICIANS.

A SPECIAL meeting of the College of Physicians of Philadelphia was held at the hall, Wednesday evening, February 18, for the purpose of hearing the report of the Commission on the Siamese Twins,—Dr. W. S. W. Ruschenberger, U.S.N., in the chair. On motion of Dr. Gross, it was, after some discussion, resolved that the *Philadelphia Medical Times* be allowed to report the proceedings of the meeting, on condition that three hundred copies of the journal should be given to the college for the use of the members.

The bodies of the Siamese Twins being upon the table, the meeting proceeded to hear the report of Drs. Pancoast and Allen. On behalf of the Commission, Dr. Pancoast stated that, the dissection not having been entirely completed, their report would be a verbal one, to be followed at some later date by a memoir upon the subject. He further remarked that it had been agreed that he should consider chiefly the surgical aspect of the matter in hand, whilst to his colleague had been assigned the demonstration of the anatomical peculiarities.

DR. WILLIAM H. PANCOAST:

Mr. Chairman, and Fellows of the College:— Having been requested, as a member of the Commission, to open the discussion this evening, I will say briefly, in reference to this monster of a symmetrical duplex development, joined, as many of the Fellows now know, at the ensiform appendix and also here at the omphalos or navel, that at the investigation which we made on the first occasion at Mount Airy I made the opening incision of the body on the line for the ligation of the primitive iliac, on the right side; Dr. Allen made the incision on the left. The object was to reach the great vessels,—the aorta and two primitive iliacs,—and to force the injecting material which we used for embalming (chloride of zinc) up the aorta and down the iliacs until it ran from the incisions made in the fingers and toes. It flowed freely through the blood-vessels in Eng, owing to the ossified condition of his arteries; the injection in Chang was, however, not so successful, owing to decomposition in the tissues and blood-vessels. It was necessary to repeat the injecting process several times in order to preserve the body. The arteries of Chang were found to be very much decomposed,—quite rotten, in fact.

In Dunglison's Medical Dictionary we find the scientific name given for the Siamese Twins, in the classification of teratology, to be *Xiphopages*; and by referring to the admirable article on Diplo-teratology of Dr. G. J. Fisher (published in the Transactions of the Medical Society of the State of

New York for the year 1866), it will be found that the twins belong in the class of *Anacatadidyma*. In his classification of double monsters he makes three orders: *Order first*,—*Teratacatadidyma*; derived from *τέρας*, *τέρας*, a "monster," *κατά*, "down," and *δίδυμος*, a "twin." *Definition*,—duplicity, with more or less separation, of the cerebro-spinal axis, from above downwards. *Order second*,—*Terata-anadidyma*, derived from *ανά*, "up" or "above," and *δίδυμος*, a "twin." *Definition*,—duplicity, with more or less separation, of the cerebro-spinal axis, from below upwards, or from the caudal towards the cephalic extremity of the neural axis. *Order third*,—*Terata-anacatadidyma*, derived from *ανά*, "above," *κατά*, "down," and *δίδυμος*, a "twin." *Definition*,—duplicity, with more or less separation, of both the cephalic and the caudal extremity of the cerebro-spinal axis, existing contemporaneously. In this order, the monster now before us might be called an *Omphelopus Xiphodidymus*.

Thus we have the scientific nomenclature of this monster. Of course, the consideration of greatest interest to the profession, and one of the main reasons why the Commission made such exertions to obtain this post-mortem, was that the American profession might not be charged with having neglected an effort to obtain an autopsy, which would solve the mystery of their union. The feature of greatest interest is connected with this band,—about four inches long and eight inches in circumference. In addition to this, there are other points of importance in teratology, in regard to the fulfilment of the law of homologous union, in relation to the juncture of the recti muscles and the fasciæ of the obliquus and transversalis at their point of meeting in the centre of the band. In regard to the position of the hearts, we think their apices present towards each other; but we have not yet opened the thorax. The livers we have found to approximate to each other and to push through the respective peritoneal openings into the band. We extended our incisions to the margin of the band in front. By placing my hand in the peritoneal cavity of Eng and my colleague placing his hand in the peritoneal cavity of Chang, we pushed before us processes of peritoneum, which ran on to the median line of the band; and we could feel our fingers in the lower portion of the band, behind the median line, with a distinct layer of peritoneum between them, demonstrating at once the prolongation of the peritoneum into the band, and the complete separation of one peritoneal cavity from the other at this median line. Above that we felt some traces of vascular connection, apparently running from one liver to the other; but this we will examine into when we have a better opportunity of carefully dissecting and examining what vascular structures may exist. We also noticed that in turning off the flaps consisting of the anterior walls of the abdomen, the hypogastric arteries, as illustrated by the diagram on the blackboard, ran upwards in each body into the band. We lost them in this way, as we

think, towards the common umbilicus in the anterior inferior surface of the middle of the band.

It is probable that the two hypogastric arteries on each side passed through this umbilicus. Whether or not there were two umbilical veins, we have not yet been able to decide, nor to answer the question whether the umbilical cord was double or single and composed of the four hypogastric arteries and two umbilical veins, or whether the placenta was single, double, or twin.

We also recognized that the ensiform appendix, as shown in the diagram of each side, was prolonged and united in the middle line. On our later examination, we find that there is complete continuity of structure of the cartilages, but no true joint at the middle line, although it is possible there may be some small synovial sacs farther up. The motion is mainly due, as I here demonstrate to you by moving these bodies one upon the other, to the elasticity of the connected ensiform appendices and intervening fibro-cartilages.

In regard to the vascular connection of the band, we have not yet been able to make so thorough and careful an examination as we wished; but still, in throwing colored plaster into the portal circulation of Chang it has been found to flow through the vessels of the upper part of the band into the portal vessels of Eng. So that the surgical anatomy of the band consists in the skin and fascia which cover it, the two separate peritoneal pouches which meet in the middle, the large peritoneal pouch, the vascular connection, to whatever extent that may exist between the two portal circulations, and the remains of the hypogastric arteries in the lower portion of the band. Thus the main difficulty in any operation for section of the band would seem to be in regard to the peritoneal processes and the portal circulation. The anastomosis which may exist between the internal mammary arteries and the intercostals in the integument in the upper portion of the band, of course would present no difficulty.

I will not venture upon any further remarks as to the surgery of the case, while there are so many distinguished gentlemen present more competent than myself to give an opinion. At the same time, operations on the peritoneum may not be considered so hazardous in this day, when ovariectomy, gastrotomy, and even Cæsarian section, are so often performed. The peritoneum-pouches themselves would not present so great a difficulty as might be anticipated, under pressure and acupuncture, by which the sensitiveness of the structure might be so altered as to permit of a section. I was informed at Mount Airy that in Paris a surgeon had made the experiment of applying pressure upon the band, and it was reported the twins had fainted in consequence. I could not ascertain, however, whether this was from fright, design, or actual pain.

As Dr. Hollingsworth is present, it may be proper for me to mention a fact which that gentleman can corroborate, that Eng was the stronger physically and Chang was the stronger mentally. The same difference was observable in their characters. Chang was more irritable than Eng, especially since an attack of paralysis with which he had been afflicted,

—this being in the side next to Eng. The latter had not only to bear with the irritability of his associate, but also to support one-half his weight. Among other peculiarities, Chang would sometimes break useful articles or throw them in the fire.

In conclusion, let me say that when I turned up the skin and superficial fascia of the H incision on the posterior part of the band, I was struck with the development and the strength of the abdominal aponeuroses. The fibres arched, interlaced, and developed into a strong fibrous band about a quarter of an inch wide, running around the median line, although there was no actual joint in the cartilage.

Prof. HARRISON ALLEN:

Mr. Chairman: I will probably best discharge the duty devolving upon me by at once proceeding to a somewhat more minute anatomical description than Dr. Pancoast has given, this being in accordance with the understanding between us in reference to the evening's exercises.

Perhaps it would be best to point to that simple diagram upon the blackboard before considering the subject more fully in detail. As Dr. Pancoast has informed the Fellows, there is a union of the twins at the two ensiform cartilages, which are very firmly joined in the centre, Eng's process being the more robust of the two. You will observe that there is a point of conjunction between the two processes which is not quite in the median line of the band. In the centre of the band is seen an elliptical space which suggests to the observer the presence of a synovial cavity. It is probable that the ensiform junction is of the character of a synchondrosis, with a median bursa-like sac; neither ensiform cartilage is ossified.

DIAGRAMMATIC REPRESENTATION OF THE BAND.

- A, upper or hepatic pouch of Chang.
- E, E (dotted line), union of the ensiform cartilages.
- D, connecting liver band, or the "tract of portal continuity."
- B, the peritoneal pouch of Eng.
- C, the lower peritoneal pouch of Chang.
- E, E, lower border of the band.

Below this point, in the diagram, you see a number of differently-lined tracks. The lower one (C),

immediately above the umbilicus, is only separated from the skin by a very delicate layer of tissue (so that, with the finger introduced into the pouch and moved, there is a decided indication of motion in the skin) on the under surface (E, E) of the band.

This pouch passes across the band from the abdomen of Chang, and is lost in the duplicature of the suspensory ligament of the liver of Eng. The finger passed upward to the band from the abdomen of Eng crosses the band above the pouch just mentioned, and is lost between the layers of the suspensory ligament of the liver of Chang. When the significance of the round ligament at the free border of the suspensory ligament is remembered, the relations of these pouches directly suggest that they have had essential bearings to the umbilical vein of the funis, and may be provisionally termed the *umbilical pouches*.

Above Eng's pouch (B), and between it and the under surface of the ensiform conjunction, is a second pouch (A) prolonged from Chang's abdomen, which fairly reaches the peritoneal cavity of Eng, but is not continuous with it. Extending up into this pouch from Chang's abdomen is a process which suggested to the Commission the possibility of the transit of hepatic vessels. This view was rendered more probable from the fact that a similar process passed up into the band from the liver of Eng. Accordingly, the plaster injection, colored by ultramarine, was thrown into a tributary of the portal vein of Chang, when it was observed that the fluid passed freely into the liver of Eng, as well as into some of the mesenteric veins proper. It is my own hypothesis that this bond of union (D) was the true hepatic tract; but in its present state, in the absence of evidence of any parenchymatous admixture about the vessels thus crossing the band, we prefer to denominate the transit as the *tract of portal continuity*.

In the foetal condition it is very likely that this large space (A), the upper pouch, now continuous with the abdomen of Chang only, was entirely occupied by true liver-tissue, which, as maturity was attained, became smaller, and left an empty space. Hence I propose to call this upper pouch the *hepatic pouch*. The contraction chanced to be greater on Chang's side, in harmony, it may be, with other evidences of a weaker and less developed type, which is so apparent in many of the tissues of Chang. Now, with reference to the demonstration. As Dr. Pancoast has already informed you, the incisions in the abdomen were made in rather an exceptional manner. By reference to the parts it will be seen that the incision in either individual was located in such a way as to avoid the median line, since it was supposed from the peculiar position of the umbilicus that the remains of the hypogastric arteries would be found extending from the fundus of the bladder upward and inward along the entire length of the anterior wall of the abdomen. Besides, this incision would enable us, by continuing from below upward, to fairly open the abdomen and examine the cord, without violating the conditions by which the Commission was bound. The flap comprises the greater part of the abdominal wall, and can be best observed,

from the position of the bodies on the table, in that of Eng.

You notice that the tissues are well supplied with fat; and this condition is very plainly in contrast with that of Chang. Eng's side of the band is well nourished; Chang's end of the band presents an entirely different aspect. Chang was an invalid, and the weaker half of this organism, with less strength in the abdominal walls, and in every way less tissue, than was possessed by Eng. You can mark that distinction very plainly in the two halves of the band, proving, if we had no other means of proof, that there could not be any very intimate communication of the vessels between the two.

The first point worthy of notice is that of an isolated mass of adipose tissue, evidently sub-peritoneal, which is in the position of the usual umbilicus, namely, in the median line of the abdomen, about half-way up the anterior wall. This is strictly symmetrical, a similar point of about the same size being found in Chang.

Another fact equally well pronounced is that in Chang the bladder was found very much contracted and contained no urine; it was deep down in the cavity of the true pelvis. That of Eng, however, was distended with urine: hence there was a contrast in the appearance of the umbilical fold in the two individuals, in consequence of the great difference in the actual size of the bladders.

My finger is now in the *umbilical pouch* of Chang (c). The motion is noticeable in the under surface of the band. On the side of Eng no such motion will be observed. I can very clearly see my finger passing between the two folds of the suspensory ligament. At this point it would perhaps be well to exhibit the drawings which have been made of the views which we have been able to obtain from this very limited incision. On looking up towards the band with the greatest possible stretch of tissue, we see the arrangement of the remains of the hypogastric arteries converging towards the bond of union. In this lower diagram we show you the livers joined by what is supposed to be the *tract of portal continuity*. You will observe the limits are somewhat symmetrical. Here is the liver of Chang, with a foreshortened right lobe.

DIAGRAMMATIC REPRESENTATION OF THE LIVERS; PORTRAYING THE RELATIONS OF THE VESSELS, ETC.

The arrows show the directions in which the injection passed from Chang to Eng.

The remainder of the right lobe is deep within the abdomen, and of course it has not been seen. Here is the fundus of the gall-bladder, and there the suspensory ligament, carrying the remains of the umbilical vein. When the finger is passed from Chang into Eng, it is received between the folds of the suspensory ligament of Eng. In Eng, the parts are essentially the same, although you see more evidence of adipose tissue. Here is a little ligament aiding in the support of the liver, to whose convexity it is attached; it is not seen in Chang at all. You might term it an accessory suspensory ligament. When the finger is introduced behind the pouch, it is observed to terminate blindly, showing, we think, that it is adventitious, due to the presence of that suspensory ligament.

We find some vessels of the portal system, even as far down as the mesentery, well filled with the blue coloring-matter. We of course desired, as far as possible, to examine all the tissues here by these incisions: hence it was that when the bodies were in this position the skin was taken off from the wall in order to get a view of the linea alba.

[The bodies were here inspected by the audience, and afterwards turned so as to expose the posterior part of the band. Further remarks apply to this posterior aspect.]

Dr. PANCOAST: While the bodies are being turned, I will take the opportunity of replying to one or two questions which have been asked me. First, in regard to the common sensibility of these individuals. According to the statements we received at Mount Airy, there was a line of common sensibility corresponding to the median line of the band. Dr. Hollingsworth says that if a pin were stuck into the band at the median line, both of the twins would feel it distinctly; but that, even at a slight distance to either side, the point of the pin produced an effect only on the twin of that side.

Another question has been asked me, as to whether either of them was ever put separately under the influence of an anæsthetic. I answer it by saying that so far as we know it never was attempted, but that when, upon the final occasion, Chang was anæsthetized by death, Eng was for a time unaffected. The story as told us at Mount Airy was that Eng waked up and asked his son, "How is your Uncle Chang?" The boy said, "Uncle Chang is cold—Uncle Chang is dead." Then great excitement took place. Eng commenced crying out immediately,—saying to his wife, whom they called in, "My last hour is come," and finally sank away. He was in perfect health when they went to bed.

They had been sitting up in a large double chair, made for their accommodation. Eng was smoking his pipe, until he became sleepy, and finally said to Chang, "We must retire." Chang said that he could not lie down comfortably. I understand that when they went from Chang's house to Eng's house [see editorial], where they died, it was against the direction of Dr. Hollingsworth; but with their usual stubbornness they persisted in riding the distance in an open buggy. To return to the narrative of the night of their death, after Chang had refused to

lie down, they walked about the house for some time, and even went out to the porch, and washed their hands and drank some water. It was about one o'clock when they went to bed. Then Chang died, some time between that and morning; his death not producing any immediate impression on Eng. It was only when the latter woke up and inquired about the condition of his brother, that he was at all affected.

As to the question, "What caused Eng's death?" I am not able to tell. The post-mortem which has been made does not show the condition of his lungs. Probably the valves of his heart were in a disorganized condition, and probably also the shock upon that weakened organ caused death.

Dr. ALLEN: In my opinion, Chang died of a cerebral clot. From inquiry at his home, I was led to believe that the lung-symptoms were not due to pneumonia; indeed, were not severe enough to have been so caused. The suddenness of the death, the general atheroma of the arteries, and the fact that there had been previously an attack of cerebral paralysis, all indicated that the death was of cerebral origin. Eng probably died of fright, as the distended bladder seemed to point to a profound emotional disturbance of the nervous system, the mind remaining clear until stupor came on,—a stupor which was probably syncopal. One thing to be settled in the making of our examination was to get the bodies in the best possible position, so that we could judge of the true nature of the band.

You will observe the great contrast between the anterior appearance of the band and its posterior aspect. When we suspended them face to face we conceived we had them in the proper position for study. On the posterior side there was a fold underneath the skin extending from the ensiform cartilage of Chang, passing over, crossing the median line, and inserted into the ensiform cartilage of the opposite twin, Eng. It was one of the objects of the examination to determine what was the nature of this fold. I judge it to be the linea alba; but I leave the Fellows to decide that for themselves. I will also add that, because we had not the privilege of cutting the anterior portion of the band, we were obliged to cut down from the point of which I have spoken to get to the structure, and demonstrate these *culs-de-sac* from behind.

Here (referring to the casts), from this point the incision is horizontal about midway, and joined laterally by two oblique lines which were directed one upward and the other downward and outward, making a modified letter-H incision. Thus we got all the space we needed. When I raise the skin, we see the scar of the umbilicus in the superficial fascia; and on lifting the other flap we get a better general demonstration.

And now we come upon the point of interest, namely, the position of the band and its true nature. We have a diagram here. You notice on Chang's side that there is an arrangement of interlacing aponeurotic fibres, marked here; and these fibres, starting in Chang, pass across the median line and are inserted into the ensiform cartilage of Eng.

Turning the lower flap downward, the upper flap upward, and the two lateral tongues outward, the superficial fascia is exposed. This is abundantly supplied with adipose tissue on either side, but is free from fat where it covered the band. Both the lower flap and the fascia are lost in the scar marking the position of the umbilicus. The same dissection exhibits the position of the lower pouch of Chang. Turning down the external oblique, the two recti, and the internal oblique muscles, the transversalis was exposed, the latter forming a very well-defined layer in Eng, with an interval between the ensiform cartilage and the inferior margin of the thorax. These were much less marked in Chang.

Turning forward this layer of fibres in Eng from without inward, the diaphragm is brought into view. Muscular fibres are conspicuous in this position. The peritoneum on either side is now fairly exposed. Incisions may now be made with a view of demonstrating the pouches of the band. The upper pouch of Chang is, you will observe, freely opened on its posterior aspect, and the vessels in the tract of portal continuity are seen to be well distended with the injecting fluid. A small artery is seen crossing beneath this tract of veins, and is probably a branch of the hepatic; but, whatever may be its origin, it evidently could have little effect in influencing the nutrition of parts beyond the band, and is probably retained within the band itself. The lower pouch of Chang reveals nothing which was not demonstrable from in front, and the same may be said of the single pouch of Eng; thus confirming our opinions of the construction of the band before the pouches had been opened from behind.

Dr. ABRAHAM JACOBI, of New York, being called upon, said: I am very much obliged to the gentleman who has mentioned my name. I do not believe, Mr. Chairman, that I have anything to add to the stock of knowledge in regard to the subject before us. If I were to answer the question as to how this monstrosity originated, especially whether they became connected after having been separate organisms, I should say that that idea has been given up by those whose opinions are entitled to weight. It is true that years ago such specimens were spoken of by Dalton in Holland; and a number of others have alluded to the idea that two such individuals might in embryonic life become united simply by adhesion, the result of their being located together in the embryo. In truth, it appears to me that at that period such a thing might be possible; but of course the union would be a superficial one, not involving the deep organs.

We know that the first epidermis is formed about the end of the fifth week of embryonic life, and that after a time it is thrown off, so that the embryo of about seven or eight weeks is more loosely covered with the real epidermis than in the earlier period. The epidermis is thrown off a number of times until about the fourth month of utero-gestation, when it is finally perfected and remains intact. Now it is suggested that at those times when the epidermis is thrown off the connection takes place between the two individuals,—just as the connection takes place between the prepuce and glans, which we so

often find adherent in the fœtus and in a number of new-born children.

There are evidences, which we cannot forget, that such connections have taken place before the final epidermis is formed, and about the time one of the earlier coverings is being thrown off, at a period when the internal organs, frequently implicated in such monstrosities, are already formed. There are few double monstrosities so well developed as this one. I think the records of about four hundred monsters have now been collected in the books and journals; but very few are of such a complete nature as this. Every one has heard of the Hungarian Twins, who lived to the age of twenty-one years, in the last century. Another pair of female twins, that travelled in Germany about two years ago, were described at the time, in the *Berliner Wochenschrift*. They were of a similar nature. There are two cases on record in which a division has been successfully attempted, but in those cases the connections were not so well developed as in the Siamese Twins. The connection was in the same neighborhood, but was only superficial,—of skin and subcutaneous tissue. One of the cases is recorded by Dr. Braun (*Virchow's Archiv*). Fortunately, or unfortunately, I do not know which, they were his own children. They were of the female sex. He separated them immediately after birth. One lived three and a half days; and when the case was described in 1866, the other was five years old. In that instance the connection—three and a half inches long—extended from the ensiform process to the umbilicus. The other case is described as early as 1689, by the old German author Kernoch.

As far as the origin of twin monsters is concerned, I am certainly of those who are not of the opinion that two individuals could get into such an intimate connection by growing together. Certainly the connection is an original one. I believe that the general opinion is now that one Graafian vesicle may have two ova, or one ovum have two nuclei; and these finally may, like the two vitelli of an egg, be closed together, surrounded by the same material, forming a single complete ovum; and thus it may be that the two are included in the same ovum. I think that this will explain also why the sex is always the same,—why they are always both male or both female. They are male in twenty or twenty-five per cent. of the cases.

Dr. H. C. Wood here asked Dr. Jacobi a question in regard to the Biddenden Sisters [an account of whom will be found in another column of this journal], as to whether they had been reported in the works on monstrosities.

Dr. JACOBI. I do not know anything about that.

Dr. PANCOAST stated that an account of those sisters was contained in a semi-popular book entitled "*Lexicon Tetraglotton*," published by Samuel Thomson, London, 1660.*

* The Editor of the *Times* is indebted to Dr. Pancoast for an opportunity of inspecting the work. The account of the Biddenden Maids is precisely that contained in the circular printed in another column, though in a somewhat different shape. The account is in a single sheet, and is evidently not a part of the original book, but has been pasted in it. In appearance it equals the body of the work in age, as shown by the color and condition of the paper; but of course it is impossible to decide with any accuracy when it was put in the book.

None of the Fellows desiring to say anything further upon the subject, on motion, the College adjourned.

DIAGRAM FROM A CAST SHOWING THE POSITION OF THE LIGAMENT, AND OF THE PRIMARY ANTERIOR INCISIONS.

During life the twins never assumed the face-to-face position in which they are here represented, and which is without doubt that of their fetal life.

STATEMENT.

Statement of Eng's widow, made to the Commission at Mount Airy.—The paralytic stroke from which Chang had suffered occurred about three years ago, when he was at sea, seven days out from Liverpool. He had been intemperate for some time previously, and had been drinking hard on board the vessel, being frequently intoxicated. He had never had mania à potu. Even when he was drunk, Eng was not affected. Two of his children had died; one from phthisis, the other apparently from apoplexy. Eng had lost five children: one each from phthisis, diphtheria, and dysentery, one from the effects of a burn, and one still-born.

Chang died Saturday, January 17. He had had a cough since the preceding Monday night. It was dry, with scanty, frothy sputum and no pain. Left lung probably involved; slight dulness on corresponding side. On Thursday, January 15, his skin was acting freely, and for that reason Dr. Hollingsworth ordered him not to venture out; but, in spite of that prohibition, he went as usual to Eng's. At the time of his arrival he had little cough and no expectoration, but loud bronchial râles were plainly heard by those around him.

When Eng saw his wife after learning that Chang was dead, he said, "I am dying," but did not speak of his brother's death. He soon afterwards expressed a desire to defecate, and this continued

for half an hour. He rubbed his upper extremities, raised them restlessly, and complained of a choking sensation. The only notice he took of Chang was to move him nearer. His last words were, "May the Lord have mercy on my soul!"

TRANSLATIONS.

CHLORAL AS AN ANTISEPTIC.

DUJARDIN BEAUMETZ and Hine state (*L'Union Méd.*, 1873, Nos. 62 and 63) that if pure albumen, muscular tissue, or urine is mixed with a solution of hydrate of chloral of the strength of at least one per cent., and placed under conditions favorable to putrefaction or fermentation, neither of these changes takes place.

They think that they have further established that this property of the solution named is due neither to the development of chlorine nor of hydrochloric acid. They made use of a similar solution as an external application, and also as an injection in various affections. They think that it had a favorable influence upon gangrenous sores, phagedenic chancres, and ulcers which had a tendency to spread into surrounding tissues. For cancerous ulcerations a somewhat stronger solution was employed: two per cent., and even more.

They recommend the use of the same solution for the injection of serous cavities,—*e. g.*, the chest in cases of pleurisy with a secretion of pus,—and also for use in affections of the bladder attended with decomposition of the urine.

HEMICRANIA CURED BY LOCAL DEPLETION.

DR. HAMON (*Bulletin de Thérapeutique*) gives an account of a case of right hemicrania occurring in his practice, which was successfully treated under the following circumstances:

The patient, a gentleman thirty-five years of age, and enjoying good general health, had been suffering for some eight months with frequently-recurring neuralgic attacks.

For some time these attacks were kept under control by subcutaneous injections of chlorohydrate of morphia ($\frac{1}{4}$ th grain); but this agent finally seemed to lose its power, and, even when combined with valerianate and sulphate of quinia and administered by the mouth, failed to give relief. Dr. Hamon then had recourse to local depletion. Some five ounces of blood were abstracted from the patient's right malar region by means of the mechanical leech. The improvement in the neuralgic symptoms was immediate and complete; the pain disappeared, and after the lapse of some months had not returned.

WILLIAM ASHBRIDGE, M.D.

TEMPORARY ALBUMINURIA THE RESULT OF COLD BATHING (*The Lancet*, December 6, 1873).—Dr. George Johnson reports four cases in which, after protracted cold baths, albumen appeared in the urine for periods varying from a few hours to several weeks. The albuminuria was probably caused by repeated and prolonged immersion in cold water, which, by repressing the cutaneous secretion, may possibly lead to permanent mischief and to structural degeneration of the kidney.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

THURSDAY, FEBRUARY 19, 1874.

EDITORIAL.

CHANG AND ENG.

IN the present article it is not purposed to give an elaborate history of these famous twins, but only to put on record certain well-ascertained facts of physiological interest in regard to their life, to give all that can be ascertained as to the circumstances of their death, and to offer a brief history of the manner in which their bodies were brought to Philadelphia.

Chang and Eng Bunker were born in Siam, in the year 1811, but lived for many years in North Carolina, where they were married, and raised large families of children, Chang being the father of ten, Eng of nine. Dr. Joseph Hollingsworth, to whom we are indebted for the information given in this article as to their habits of life and the circumstances of their death, states that he has known them as residents in the neighborhood of Mount Airy, North Carolina, for some twenty years, during which time he has acted as their family physician. Chang, who is said to have derived his name from the Siamese word for "left," was the left of the pair, and was much smaller and more feeble than his brother Eng, whose name signifies "right." Their habits were very active: during the latter part of their life they and their families lived in two houses, about a mile and a half apart, and it was an inflexible rule that they should pass three days alternately at each house. So determinedly was this alternation maintained that sickness and death in one family had no effect upon the move-

ments of the father, and a dying or dead child was on one occasion left in obedience to it: indeed, Dr. Hollingsworth is very positively of the opinion that the death of the twins themselves was the result of this rule, or, at least, was materially hastened thereby. This will be made apparent hereafter.

The evidences during life that the twins were physiologically distinct entities were very numerous and apparent. They were different in form, tastes, and disposition; all their physical functions were performed separately and unconnectedly. What Chang liked to eat, Eng detested. Eng was very good-natured, Chang cross and irritable. The sickness of one had no effect upon the other, so that while one would be suffering from fever the pulse of the other would beat at its natural rate. The twins not rarely suffered from bilious attacks, but one never suffered at the same time as the other; a circumstance which seems somewhat singular in view of the close connection which the post-mortem has shown to exist between the livers of the pair. Chang drank pretty heavily,—at times getting drunk; but Eng never felt any influence from the debauch of his brother,—a seemingly conclusive proof that there was no free interchange in their circulations.

The twins often quarrelled; and of course, under the circumstances, their quarrels were bitter. They sometimes came to blows, and on one occasion came under the jurisdiction of the courts. After one of these difficulties Chang and Eng applied to Dr. Hollingsworth to separate them, stating that they could not live longer together. Eng affirmed that Chang was so bad that he could live no longer with him; and Chang stated that he was satisfied to be separated, only asking that he be given an equal chance with his brother, and that the band be cut exactly in the middle. But as Dr. Hollingsworth advised very decidedly against this, and declined to interfere, cooler counsels prevailed.

In August, 1870, Chang suffered from a paralytic stroke, from which he never fully recovered; and during the last year of his life he several times said to Dr. Hollingsworth, "We can't live long."

On the Thursday evening preceding their death, the time having arrived for their departure from the house at which they were staying, the twins rode a mile and a half in an open wagon. The weather was very cold,—the night being the severest of the winter. Chang had been complaining for some days of cough, with distress and actual pain in the chest. He was so unwell that his wife thought he would be unable to bear the trip; but he finally went. On Friday morning Chang reported that he felt better, but that in the night he had had such

severe pain in the chest, and so much distress, that he thought he should have died.

The twins slept in a room by themselves or with only a very young child present; and some time in the course of Friday night they got up and sat by the fire. As they were accustomed to do this frequently, nothing was thought of it by those of the family who saw them, even though they heard Eng saying he was sleepy and wanted to retire, and Chang insisting on remaining up, stating that his breathing was so bad that it would kill him to lie down. Finally, however, the couple went to bed again, and after an hour or so the family heard some one call. No one went to the twins for some little time, and, when they did go, Chang was dead, and Eng was awake. He told his wife that he was very "bad off," and could not live. He complained of agonizing pain and distress, especially in his limbs. His surface was covered with a cold sweat. At his request his wife and children rubbed his legs and arms, and pulled and stretched them forcibly. This was steadily continued until he went into a stupor, which took place about an hour after the family were alarmed. The stupor continued up to death: according to the statements of the family, there were no convulsions.

Dr. Hollingsworth did not reach the house until after the death of both of the twins. He found the wives, and especially the children, averse to any post-mortem being made, but, after much persuasion, obtained permission to put the bodies in a position to be preserved until he could obtain some one from Philadelphia to perform the autopsy. He placed the bodies, after they had been thoroughly cooled, in a coffin, which was put in a wooden box, which was, in its turn, enclosed in tin; the whole being buried in a dry cellar in such a way as to be imbedded in charcoal.

As bearing upon the question, What was the cause of the death of Chang? it is important to state that Dr. Hollingsworth had repeatedly told Chang and Eng that, in his opinion, the death of one did not necessarily compromise the life of the other; that he could separate them, by cutting close to the body of the dead one, without killing the living one. It would appear possible, in view of this, that the death of Eng was not simply the result of fright.

SHORTLY after the death of the Siamese Twins, Dr. William Pancoast requested the Mayor of Philadelphia to telegraph to the Mayor of Greensboro', North Carolina, in regard to the possibility of a post-mortem examination being obtained. To

this the Mayor of Greensboro' substantially replied that he had neither knowledge nor power in the matter. When Dr. Hollingsworth, *en route* North, arrived at Greensboro', the telegram of Dr. Pancoast was handed to him. On the evening of his arrival at Philadelphia (Friday) he saw Dr. Pancoast and Prof. Gross, and a letter was written to the wives of the twins, proposing that Dr. Pancoast should come on to embalm and examine the bodies.

On Sunday Dr. Hollingsworth saw Prof. John Neill, and, on consultation, it was concluded that the matter was of public importance, and should not be confined to any single private individual. As the promptest method, it was deemed best to call a meeting of such physicians as were interested in the matter and could be hastily got together.

The meeting took place on the evening of Monday, January 26, 1874, at the house of Dr. Neill; but, although a number had been asked, only Prof. Leidy and Dr. Ruschenberger, besides Drs. Hollingsworth and Neill, were present at the conference. As the result of their deliberations, it was determined that two gentlemen should be at once dispatched to the homes of the twins, in order to examine and embalm the bodies as speedily as possible; and it was agreed that Drs. William H. Pancoast and Harrison Allen should be requested to go.

It will be seen at once that the College of Physicians was in no wise responsible for the acts of the Commission, although its name was freely used by the prominent Fellows engaged in the transaction. Indeed, these gentlemen, recognizing this, were prepared to meet the expenses of the trip had the College failed to endorse their action.

Owing to various obstacles and embarrassments, the Commission did not leave the city until Thursday night, January 29. At the request of Dr. Pancoast, Dr. Andrews went with the party as a companion and aid.

The Commission arrived at Mt. Airy on the evening of Saturday, January 31, and proceeded to the residence of Eng the following morning, in company with a photographer and Dr. William Hollingsworth, who is the family physician in the absence of Dr. Joseph Hollingsworth. The widows of the twins received the Commission hospitably, and a conference was at once entered into, at which the "Mistresses" Bunker, the Commission, Dr. Hollingsworth, and the widows' legal adviser were present. It was then agreed that, under consideration of embalming the bodies of the twins, permission would be granted to exhume and examine the structures distinguishing them, provided that no incisions should be made which would impair the ex-

ternal surface of the band. Subsequently it was agreed that limited incisions would be allowed on the posterior surface of the band. An agreement in writing was then drawn up, expressing the above restrictions, but extending authority to the Commission to remove the bodies to Philadelphia, provided that they be kept there in a fire-proof building, and held subject to the commands of the families when informed of the completion of the embalming process.

The object of the visit of the Commission, having been noised about the country, had attracted a crowd of curious people, who were willing enough to give the necessary aid in exhuming the bodies. The circumstances attending this were briefly as follows. The bodies were buried in the cellar of Eng's house, in a shallow grave, which had been covered with a tumulus of powdered charcoal. This being removed revealed several planks covering an outer wooden box, which, in turn, enclosed a tin encasement to the coffin. After unsoldering the tin box, the coffin was carried to the second floor of the house, to a large chamber. The lid was unscrewed, and the object of the search of the Commission was exposed to view. It was certainly an anxious moment. Fifteen days had elapsed since death, and no preservative had been employed. It was an agreeable surprise, therefore, that no odor of decomposition escaped into the room, and that the features gave no evidence of impending decay. On the contrary, the face of Eng was that of one sleeping; and the only unfavorable appearance in Chang was a slight lividity of the lips and a purplish discoloration about the ears. The widows at this point entered the room, and, amid the respectful silence of all present, took a last look at the remains.

The room was then cleared of all not connected with the work of the Commission; the bodies were disrobed, and preparations at once begun to secure photographs. The bodies were held in an erect position, and negatives of the entire figures, and views of the band at short foci, were secured. The day being cloudy, much time was necessarily expended in obtaining these pictures,—time sufficient for a number of observations upon the external appearance of the bodies to be recorded. The notes are given just as they were taken at the time:

Examination made Sunday, February 1, 1874, fifteen days and eight hours after the death of Chang.

The bodies were found in the coffin in a good state of preservation; there was a slight cadaveric odor about Chang, with marked passive congestion of the back of the arms and neck on both sides, and in a less degree

of the posterior aspect of the forearms, buttocks, thighs, and legs; there was none on the feet, where, however, there was marked fulness of the superficial veins; this was better marked on the left side. There was a greenish discoloration on the anterior abdominal wall.

Face.—Lips moist and discolored; peculiar reddish congestion sparsely distributed over malar prominence and beneath ear. The thoracic discoloration was much deeper on the side next to Eng.

The left nipple was visible in front well towards the middle line, the right one just showing. The fingers of the right hand—the paralyzed side—were forcibly flexed, although *rigor mortis* was absent.

In Eng there was passive congestion of back, most marked on buttocks and infra-spinous spaces—none on the front of the body; slight greenish discoloration of anterior abdominal wall.

In both subjects the hair of the head was gray.

On the *pubis* of each subject the hair of the *left side* was gray, that of the *right side*, black.

The process of embalming was now begun. Incisions were made to the outer side of the median line of the abdomen in each individual, extending from the inferior margin of the thorax to a point midway between the symphysis pubis and the anterior superior spinous process of the ilium. The aorta was reached after the usual method, but was found to be in an atheromatous condition, compelling the selection of the left primitive iliac for the insertion of the pipe. A solution of chloride of zinc was then injected.

After the embalmment had been completed, the incision was continued upward and inward towards the band. Examination of the band through this incision convinced the Commission of the complex nature of the band, and suggested the suspension of a complete study of the parts until removal of the bodies to Philadelphia. The fact that the photograph had been far from satisfactory strengthened the Commission in its decision to stop the investigation at this stage. The incisions were, therefore, sewn up, the clothing readjusted, and the bodies placed in the coffin and conveyed to Mt. Airy. Here the tin box which was used for the temporary burial was again brought into use, and the lid carefully resoldered. Without delay the Commission started on its return, expressing the bodies at Salem.

The Commission arrived in Philadelphia, February 5, having been absent one week.

Upon the arrival of the bodies at the College of Physicians, they were placed in the care of the committee upon the Mütter Museum and of the Hall Committee, and were closely locked and guarded until a special meeting of the College was called, upon Monday evening, February 8, when, after

considerable discussion, it was agreed that the College should accept the action of its Fellows and pay the expenses of the trip. Further, a vote of thanks was given to the gentlemen who went to North Carolina, and to Dr. Hollingsworth, and the Mütter Committee was authorized to appropriate three hundred and fifty dollars for the preparation of casts and photographs, which should remain the property of the Museum. Finally, the College appointed the Mütter Museum Committee and the original Commission (Drs. Pancoast and Allen) as a joint committee for carrying out the examination of the Siamese Twins; it being understood that a report and a demonstration of the specimens were to be made to a subsequent meeting of the College; also, that the dissections and the report were to be the work of the original Commission.

On Tuesday, the 10th instant, they were exposed for study: they were at that time found in a satisfactory condition, except the right lower extremity of Chang, which required immediate care to prevent further destructive changes taking place.

THE OLD SAD STORY.

WE learn from the London *Lancet* that Mr. Webb, editor of *The Medical Times and Gazette*, recently died suddenly at the age of forty-seven,—just at the time when brilliant professional success was coming to him,—leaving a widow and ten children to struggle through poverty, aided only by an annual income from settled property of about six hundred dollars a year. Surely it is a wrong system which brings remunerative labor only at an age when other men are thinking of the long rest that finally comes to all.

WE have received an essay from its anonymous author entitled "Homocultology," in which it is proposed to cure the human flesh of ills physical, mental, and spiritual, by castration, so as to prevent the perpetuation of any but perfect types. We can only say that in this case we think "charity should commence at home."

SIR SAMUEL BAKER asserts his belief that Dr. Livingstone is still alive. His speech before the Royal Geographical Society appears to have convinced Sir Henry Rawlinson and the Society that the probabilities are in favor of Dr. Livingstone's being still alive.

THE BIDDENDEN MAIDS.

WE are indebted to Dr. Walter F. Atlee for a cake or cracker, about four inches long by two inches broad, which, with the circular that is copied below, was given him some years since by a patient who had lately come to this country from Biddenden, England. The man stated that the crackers were doled out year after year as directed by the will of the sisters, and as had been done regularly since their death. The circumstance is very interesting, as showing the way in which these old foundations are maintained in England for many centuries. Scientifically, the chief interest attaches to the fact that these two individuals, although so closely joined, lived for over thirty years. The union appears to have been more close than that between the Siamese Twins.

The cake is apparently a water-cracker, and is in the shape of a tomb-stone with a figure of the twins upon its face. This effigy represents two women joined together as in the accompanying wood-cut, clad in short, very low, tight-laced bodices, and hooped skirts, with gigantic mammæ, of singularly perfect workmanship, above the bodices. Over the figures is an inscription like that in a similar position upon the wood-cut here given. On the skirts of one of the figures is,—

IN

1100

on the other is,—

A

34

Y

Below the figures is the word "Biddenden."

The wood-cut on our next page is a fac-simile of that upon the circular.

We have afforded this matter so much room in today's issue because, so far as we know, these ladies have not elsewhere figured in a scientific journal. As they were evidently covetous of posthumous fame, we doubt not that their manes will be most grateful to us for thus honoring them, after nearly eight centuries, during which they have waited for embalming.

We are informed that there is in existence a very old English book containing receipts and accounts of what are vulgarly known as "curiosities," in which these faithful sisters and fast friends are spoken of in detail. Unfortunately, we have not been able to obtain a sight of the volume.

We see no reason for doubting the authenticity of the record. The statement that the twins died within six hours of each other is strong internal

evidence of its truth, since an ignorant person making up an account would not be likely to conform so closely to the facts of experience.

A SHORT AND CONCISE ACCOUNT OF
ELIZA & MARY CHULKHURST,
WHO WERE BORN JOINED TOGETHER BY THE HIPS AND SHOULDERS,
IN THE YEAR OF OUR LORD, 1100,
AT BIDDENDEN, IN THE COUNTY OF KENT.
COMMONLY CALLED
THE BIDDENDEN MAIDS.

THE reader will observe by the Plate of them, that they lived together in the above state Thirty-four Years, at the expiration of which time one of them was taken ill and in a short time died; the surviving one was advised to be separated from the Body of her deceased Sister by dissection, but she absolutely refused the separation by saying these words,—“As we came together we will also go together,” and in the space of about Six Hours after her Sister’s decease, she was taken ill and died also.

By their Will, they bequeathed to the Churchwardens of the Parish of Biddenden and their Successors Churchwardens for ever, certain Pieces or Parcels of Land in the Parish of Biddenden, containing Twenty Acres, more or less, which now let at 40 Guineas per annum. There are usually made in commemoration of these wonderful Phænomena of Nature, about 1,000 Rolls with their Impressions printed on them, and given away to all Strangers on Easter Sunday after Divine Service in the after-

noon: also about 300 Quartern Loaves and Cheese in proportion, to all the Poor Inhabitants of the said Parish.

CORRESPONDENCE.

EXCESSIVE FECUNDITY.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

RECENTLY there have come to my notice the facts of a somewhat remarkable case,—that of a lady who had eight living children in the short space of two years, four months, and twenty-four days: three children born on the 8th of January, 1742, all of whom died on the same day; three children born on the 3d of March, 1743, all of whom died on the same day; two children born on the 1st of June, 1744, one of whom died on the same day, the other lived to be twelve years of age.

Yours truly,

T. H. ANDREWS.

PHILADA., Jan. 22, 1874.

INSOMNIA.—Dr. E. P. Hurd, of Newburyport, Massachusetts (*Boston Medical and Surgical Journal*), in his address before the New Hampshire Medical Society, states that he has found chloral hydrate especially useful in the insomnia of infants. One grain may be given to a restless infant every hour till sleep is induced. Gelsemium admirably fulfils many of the requirements of a hypnotic, for its action seems to be largely that of an exalter of sympathetic function, while it lessens cerebral congestion. Three drops of tincture of gelsemium, with three of laudanum and ten grains of bromide of potassium, every two hours, have succeeded in breaking up insomnia when other remedies have failed.

TREATMENT OF ACUTE ARTICULAR RHEUMATISM BY MEANS OF IMMOVABLE BANDAGES.—In the *Archiv d. Heilk.*, Heft 5, 1873, Dr. Oehme relates his experience of the above means of treatment in forty-five cases of rheumatism. After comparison with various means of treatment employed in forty-five other similar cases, Dr. Oehme stated the following results in favor of the bandage system: 1. The pain is considerably lessened; 2. The duration of the fever is much shortened; 3. The duration of the whole attack is considerably abbreviated.—*London Lancet*.

POISONING BY THE ACID PERNITRATE OF MERCURY (*The Lancet*, January 3, 1874).—H. Stanley Gale reports a case of lupus of the cheek with red and soft but non-ulcerating tubercles, in which the pernitrate of mercury was applied over a space not larger than a florin. The pain caused was excessively acute. In about ten hours there came on a sudden, profuse vomiting of yellowish matter, together with griping and purging, the motions being streaked with blood. There were also cold sweats, with a sense of constriction about the pharynx. The pulse was small, and only 56. The vomiting was increased even by the use of ice, and came on every five or ten minutes for three hours, after which there was a tendency to sleep, and the symptoms gradually diminished in severity. The patient was a strong, healthy man, in the prime of life.

A NEW SYMPTOM OF BROMISM.—Dr. Hayden records (*Irish Hospital Gazette*, February 2, 1874) green vision as having been caused by bromide of potassium in a case under his care.

REVIEWS AND BOOK NOTICES.

DISEASES OF THE EAR, INCLUDING THE NECESSARY ANATOMY OF THE DIFFERENT PARTS OF THE ORGAN IMMEDIATELY PRECEDING THE CONSIDERATION OF THE DISEASES OF THESE PARTS. By A. D. WILLIAMS, M.D., formerly Lecturer on Otology in the Miami Medical College, St. Louis, Mo. 8vo, pp. 290. 1873.

The fresh impetus imparted to otology by the introduction of Trötsch's mirror, and the rapid progress being achieved in this branch, are shown by the numerous works relating to this subject that are constantly appearing. The past year has been a very prolific one in otological literature: a fifth edition of Trötsch, comprising nearly 550 octavo pages, has appeared, and St. John Roosa, Weber-Liel, Keen, and Dalby have each issued during the past year respectable-sized tomes upon diseases of the ear. To this list must be added a number of lesser lights,—authors ambitious to erect unto themselves monuments more enduring than brass by audaciously adding to the already vast bulk of otological literature. New methods of investigation and treatment are being constantly instituted in this, until so recently, much-neglected branch. Let not the general reader, however, for one moment suppose that all of these recent publications are issued upon such justifiable grounds, or that they are always based upon extended clinical observations. It is remarkable what a sameness not only of matter but also of manner he will find in many of them, reminding him forcibly of what has been aptly styled "rehash." Certainly, much of his reading will strike him as being stale, flat, and unprofitable. It is the old story, "Of making many books there is no end:" fortunately, their perusal does not always entail the "much study" which is "a weariness of the flesh."

This book of Dr. Williams is one of the latest accessions upon our table. Being prefaced as representing "particularly Western ideas," and claiming to be the pioneer work on diseases of the ear of "the Great Mississippi Valley," we have read the entire book with avidity, in the illusive hope of discovering in what manner Western ideas upon otology differed from our own stereotyped notions; in the hope of finding something characteristic of Western energy,—some new idea really worthy of the Great Mississippi Valley, that destined centre of American wealth and culture. Alas for great expectations! The book, lacking in thoroughness and original research, has, like the surface of that great valley, a decided tendency to flatness.

The "necessary" anatomy of the different parts of the organ with which the author prefates the consideration of the diseases of the several divisions of the ear, though in the main correct, is surprisingly limited in quantity, and we doubt whether the veriest student's compendium would be found containing less.

Tenotomy of the tensor tympani muscles is spoken of as a possible means of relieving the tinnitus aurium so frequently attending the dry catarrhal inflammation of the middle ear. But it is very evident that this operation has not yet been attempted, as might be expected in one so manifestly conservative in his practice, hesitating to use mild astringent or alterative injections; who even points out (p. 123) the danger of forcing air into the cranial cavity (!) by forcibly inflating the drum.

The author avoids applying blisters behind the ear in children, having several times received "anything but benedictions from the mother." 'Tis a pity that all patients or their friends do not see the propriety of heaping "benedictions" upon those who cruelly torture them with blisters over the mastoid process, where they

are usually as efficacious as huge bill-posters upon a dilapidated wall are in preventing its ultimate destruction.

The colored lithograph is frightful: "opacification" of the membrane by inflammatory deposits, and of the text by careless proof-reading, are alike objectionable.

As to selecting this book,—to those who have the inclination to possess but a single thorough treatise upon the diseases of the ear, our advice is similar to that given by Punch to the young man with his matrimonial schemes: "Don't."

R. M. B.

THE ANATOMIST'S VADE-MECUM. By ERASMUS WILSON, F.R.S. Edited by GEORGE BUCHANAN, A.M., M.D., assisted by HENRY E. CLARK, M.R.C.S. Ninth Edition. Philadelphia, Lindsay & Blakiston, 1873.

Wilson's Anatomy has for many years been a favorite text-book with students, and it is not likely to lose ground by the appearance of this last edition. Professing to be merely a compendium and a guide-book for the student or the busy practitioner, and not laying claim to the rank of a complete treatise on anatomy, it yet contains nearly all the facts in connection with the construction of the body which are necessary in the diagnosis and treatment of disease. Much new material has been added, many passages completely rewritten, a number of fresh wood-cuts inserted, and, with a few unimportant exceptions, the book has been brought up to the level of the present day.

GLEANINGS FROM OUR EXCHANGES.

MANIPULATION IN THE TREATMENT OF SPRAINS (*New York Medical Journal*, January, 1874).—Dr. William R. Fisher reports the following interesting case:

A young woman fell from the top of a step-ladder and severely sprained her right ankle. The local application of ice and other antiphlogistic treatment enabled her at the end of ten days to make a short journey to her home. This was, however, followed by increased pain, swelling, and inflammation, which were again subdued by rest and cold dressings. During the next three months her foot improved slightly under the use of stimulating liniments; but by another fall she lost what little had been gained since the first accident. Iodine and frictions with camphorated oil reduced the pain and swelling and increased the motion at the ankle-joint, but this articulation remained weak and painful whenever use was attempted, and a point just below the external malleolus was exquisitely sensitive to pressure or upon motion. Five months after the original accident she entered a hospital; absolute rest in bed was enforced for two months, but when she got up her foot and ankle proved to be as useless as before, and her general health was decidedly impaired.

Galvanization, repeated blisters, and uniform pressure with wet sponges, as well as quinine, iron, and similar remedies, were all unproductive of any permanent good; and finally it was resolved to submit her to the treatment by manipulation. At this time she could walk a little upon crutches, using her left foot alone to receive her weight; there was an oedematous puffiness about the right ankle almost obliterating the malleoli; the foot had a bluish, dusky hue throughout, arising from a want of active circulation; the temperature of the right leg and foot was lower than that of the left. Pressure over the instep caused a soreness, along the skin below the external malleolus a sharp, darting pain. Passive movement at the ankle in the direction of flexion or extension, and especially lateral motion inward, excited the same sharp pain. Voluntary move-

ment was confined to the toes, and even there, required considerable effort for its performance.

The repeated attacks of acute inflammation in this case had probably been the cause of its long duration, and had resulted in the formation of an unusually large amount of plastic exudation and fibrinous adhesions. The indications all pointed to the sluggish circulation in the ankle and foot as the chief obstacle to improvement.

Treatment was commenced by a general kneading and shampooing of the limbs and body until the patient had become used to the process, but after a few days the manipulations were performed as follows: The whole limb from the knee down was first rubbed and kneaded for twenty minutes, lightly where the parts were tender, forcibly where the pressure was well borne. The skin was sponged with water and dried with a towel whenever the epidermis became dry and heated by the friction. The toes were passively exercised in various directions, and the ankle-joint was flexed and extended; the extent of movement being governed by the amount of pain it produced. These manœuvres occupied about five minutes, and were followed by the kneading and frictions a little more forcibly administered, which in turn gave way to the passive movements until the whole had continued for an hour and twenty minutes. At its termination there was a decided increase of motion and diminution of pain. This was repeated daily, the movements of the joint being gradually increased in force and length of the application, while the kneading and frictions were lessened.

On the seventh day of treatment, passive motion of the joint was free in every direction and entirely painless; the adhesions had all given way as the force of the manipulations had been increased, snapping audibly one after the other; the foot was warm, there was no puffiness, and she was able to wear the same-sized shoe on the right as on the left foot. After twenty-one days of treatment, she gave up crutches altogether, and four days later she went to the sea-shore. Since then her progress has been steady, and she is practically cured.

Dr. Fisher believes that of all the means which are recommended for the treatment of sprains, manipulation is the simplest, the easiest in application, and the most efficacious. Quoting from M. Bizet, he says, "The cure by manipulation is the more prompt and certain in proportion as the remedy follows upon the accident, and it may be wrought both in simple and in complicated sprains, except in the case of fracture of the articular extremities."

TRANSFUSION OF BLOOD (*The British Medical Journal*, January 10, 1874).—Henry M. Madge, M.D., considers in detail the various forms of transfusion now in vogue which have been attended with the greatest success:

Transfusion with defibrinated blood.—The great advantage of this form is that there is no fear of clotting. The balance of scientific opinion is in favor of the theory that fibrin as it exists in venous blood is a waste product, and that the real revivifying element is the oxygen contained in the red corpuscles; but, be this as it may, the real reason for getting rid of the fibrin is that it interferes with the operation.

The blood must be carefully whipped with a *clean* fork, stick, or glass rod, and strained through fine linen two or three times. In the instruments which have been devised for using defibrinated blood, the great aim seems to have been to prevent air from entering the veins; but no special apparatus is necessary, and a common syringe has often been used with success.

2. Mediate transfusion with pure blood.—The advocates of this plan maintain that fibrin is an essential element of the blood,—that it favors coagulation,

helps to build up the tissues, and that when its removal is attempted there will always remain small particles or shreds which may produce pyæmia or embolism. It is certainly true that in many cases of recovery from impending death, after transfusion with defibrinated blood patients have died in a few weeks from pyæmia; but of course this may have arisen from various other causes.

With pure blood, however, clots are apt to form and block up the instruments; and, what is of more consequence, small clots may enter the vein, and lead, like carelessly defibrinated blood, to pyæmia and embolism.

Until recently it was thought important that a high temperature should be maintained to prevent coagulation; but it is now known that that process is rather favored by heat and is retarded by cold. The hurry to get through this form of the operation, for fear of clotting, is certainly one of its drawbacks. The great point is to have everything ready, and not to take the blood from the arm of the donor until the arm of the patient is prepared and ready to receive it.

The quantity used has been from four to twelve ounces, or in one case twenty ounces.

The entrance of air into the veins has always been one of the bugbears of transfusion, but there is now reason to think that too much has been made of it. Oré has shown that a small quantity of air thrown into the femoral vein of a dog does no harm; so, although of course the less air admitted the better, one need not be afraid in case of emergency to use an ordinary syringe.

3. Immediate transfusion from vein to vein.—It has been objected to this method that the blood thus used contains all the impure *débris* of the tissues, and must, therefore, be injurious; but the veins are certainly proper receptacles for venous blood, and once in the patient's system it soon becomes arterial. The current of blood in the veins being without impetus, the difficulty of sending blood from vein to vein has been simply and ingeniously met by Dr. Aveling. This instrument consists of a small india-rubber tube, about a foot long, with a bulb in the centre. The ends are supplied with canules for entering the veins, and the blood is propelled along the tube by a manipulation of the bulb and of the tube itself, a knowledge of which can be acquired only by practice.

4. Immediate transfusion from artery to vein.—This is the oldest form of transfusion, and has the advantage that the blood is purer than in the other varieties. Whenever it is used, the blood of the lamb is employed, as opening an important artery in the human subject is generally considered too serious an undertaking. The animal must be firmly secured by straps, the slightest movement being fatal to the operation. Dr. Madge thinks that, in the present state of our knowledge, each of these four principal forms may be employed with an almost equal chance of success.

ICE CLYSTERS IN THE TREATMENT OF DYSENTERY (by Dr. Bodo Wenzel).—In my travels during the past and present years, in the position of ship-surgeon, to Havana, New Orleans, and New York, I had occasion to treat a large number of cases of dysentery, both on shipboard and on land. Among the various agents to which I was compelled to resort in obstinate cases, one showed itself especially beneficial, and at the same time extraordinarily simple, cheap, and innocuous in application. So far as I know, it has never been used in general practice. I refer to clysters of ice-water, or rather of finely-powdered ice.

I was led to adopt this treatment in the following way. On the passage from New York I had on the vessel one extremely aggravated case of dysentery. It was characterized by high fever, severe pains in the abdomen, and especially by so exceedingly abundant hemorrhages with the very frequent stools, that the loss of blood alone involved direct danger to life, and induced me to order

in symptomatic treatment ice-water clysters every two hours.

A surprisingly happy effect ensued; not only in the fact that the hemorrhages immediately checked up and ceased altogether, but also in the almost immediate abolition of the distressing tenesmus, with a reduction of the whole febrile process. I ceased all other medication. The patient himself, so soon as he felt the least manifestation of pain, called for ice-clysters at once, and, under their use alone, this case, one of the worst which I have ever seen, so far recovered in fourteen days that he went ashore at Hamburg with good appetite, etc.,—in short, in perfect health.

Encouraged with this experience, I tried this treatment in less severe and in chronic cases, also on myself, for I did not escape attack, when I found that in all the acute and recent cases, light as well as severe, the same excellent results followed. I was compelled to use only rarely small doses of opium in addition. In most cases the medication mentioned was the sole treatment. On the other hand, I must say that in chronic dysentery, in old and recurrent cases, this means, like all others, is of less or only of transitory benefit.

I am justified in stating, then, that *in all acute and recent cases an energetic local antiphlogosis is a most effective, perhaps the most effective, treatment of dysentery.*—*Berliner Klinische Wochenschrift*, Dec. 1, 1873; from *The Clinic*.

CASE OF INTRA-RECTO-ABDOMINAL MANUAL EXPLO-
RATION (*New York Medical Journal*, February, 1874).

—Dr. Leale reports the case of a woman, æt. 45, who, while suffering intensely from an attack of dysmenorrhœa, drank, with suicidal intent, two ounces by weight of pure chloroform. She was seen half an hour after, at which time she was profoundly anesthetized, and had not vomited. Free emesis was produced by salt-and-water, but the ejecta did not emit the slightest odor of chloroform, while at the same time the expirations were strongly charged with its vapor. The stomach was washed out by means of a pump, and about a pint of water (100° Fahr.) was injected to act as a brisk diuretic. Her pupils were moderately dilated, and did not respond to light; conjunctiva insensible. Within half an hour the pulse-rate increased from 72 to 140, the heart's action growing very feeble; the surface of the body became cold and cyanotic, and death from asthenia was evidently impending. At this time the hand was cautiously carried through the sphincter ani, passed along the rectum and the sigmoid flexure into the descending colon. Direct irritation of the solar plexus of the great sympathetic nerve was then employed, and the hand carefully withdrawn.

A return to consciousness speedily followed, and the case resulted in complete recovery.

SUSPECTED PREGNANCY—FOREIGN BODY IN THE
BLADDER (*The Lancet*, January 24, 1874).—Mr. T.

W. Hine relates the case of a girl, æt. 17, who was admitted to the Hospital for Women, having been dismissed from her situation on suspicion of being pregnant. She had not menstruated for six months; her abdomen was very prominent; her breasts were large and full, the nipples firm and projecting from a dark, well-defined areola, which was studded with enlarged follicles; there was no milk; she had had severe attacks of vomiting. Since the cessation of menstruation she had suffered from temporary attacks of incontinence of urine, and had not passed more than a wineglassful at any time, but micturition was painless. The urine was thick, dark, turbid, and offensive. On passing a metallic catheter into the bladder a large calculous mass was struck, and was subsequently removed with the lithotrite. It proved to be a tooth-brush handle encrusted with urates and phosphates. The girl admitted having

used it to relieve stoppage of urine. In a week she was discharged well, and twenty-five days afterwards she menstruated for the first time in seven months.

THEORETICAL AND EXPERIMENTAL RESEARCHES ON
THE CAUSES AND MECHANISM OF THE CIRCULATION IN
THE LIVER—THESIS BY M. ROSAPPEL (M. DUVAL).—
In considering the hepatic circulation, M. Rosapelly first endeavored to define clearly thoracic aspiration and to determine its variations; he then passed directly to the study of the venous circulation of the liver, touching on the arterial circulation only so far as it enabled him to establish his conclusions. The methods used in these investigations were the same as those employed by Marey and P. Bert in exploring other parts of the circulatory apparatus. He found that thoracic aspiration, although periodically increased in intensity at each inspiration, is continued throughout the whole respiratory act, and that its principal cause is the dilatation of the mediastinum by the pulmonary retractility or elasticity. This elasticity, which is never satisfied unless there is an artificial opening in the walls of the chest, prevents all the force of the atmospheric pressure from being exercised on the organs situated in the mediastinum: these organs, therefore, are only subjected to a negative pressure, which of course is greatest during inspiration; for at that time, the thorax being dilated, there is a larger surface to be acted upon.

The author also proves that the action of the diaphragm produces an effect on the portal vein just the reverse of that which the thoracic aspiration exercises on the vena cava and the hepatic veins. Hence it results that at each inspiration two causes concur to accelerate the current of blood in the liver,—viz., the increased pressure in the portal vein, and the diminished pressure in the hepatic veins. These causes, on the other hand, retard the blood-current during expiration.

It is to be regretted that no mention has been made of the influence of the vaso-motor nerves on the blood-vessels of the liver; but, notwithstanding this omission, M. Rosapelly's researches have gone far towards filling an important gap in the physiology of the circulatory system.—*Le Mouvement Médical*.

LOSS OF THE UPPER EXTREMITY AND SCAPULA—RE-
COVERY (*The Lancet*, January 3, 1874).—Dr. Katho-

litzky reports the case of a bricklayer, aged 37, who was caught in a piece of machinery in such a manner that his right arm and shoulder-blade were instantly torn off. He was seen an hour and a half after the accident; the wound was about ten inches long and eight inches wide, and extended downwards from the acromial end of the clavicle along the right side of the chest. The hemorrhage was inconsiderable, and no bleeding or pulsating vessel could be discovered. The action of the heart was extremely weak, with eighty pulsations per minute, and the right subclavian artery could hardly be felt. The size of the wound was diminished by bringing up the margins and holding them *in situ* by means of steel clamps; compresses were placed under the clavicle, and held in position by a bandage passing over the sound shoulder, and an iced water-dressing was applied. The pain was relieved by hypodermic injections; carbolic acid was added to the dressing on the third day, when superficial gangrene occurred; and on the fourteenth day the greater part of the wound had closed by first intention. Seven weeks after the accident the cure was complete.

ARSENICAL PAPER HANGINGS.—“Arsenic occurs not only in the bright papers, but also occasionally in the white or cream-colored enamel paper so frequently used for drawing-rooms, and in drab papers tinted with ochre.”—*The Lancet*, January 3, 1874.

MISCELLANY.

ORIGIN OF GUM.—According to the researches of various German investigators, gum is the product of a retrograde metamorphosis of cellulose. Mohl (*Botanische Zeitung*, 1857, p. 33) found that the cells of the pith and the medullary rays of a species of *Astragalus* at first had a normal appearance, and offered a cell-wall composed of ordinary cellulose. As the plant increased in age the walls of these medullary cells underwent a change, which affected first the outer layers of each wall, and extended irregularly towards the centre of the cell. By this change the cellulose was converted into tragacanth. Wigand has studied the formation of arabin and bassorin (*Jahrbücher f. wissenschaft. Botanik*, 1861, iii. p. 117) in the stem of the plum. According to his researches, the bassorin is formed first, and the arabin is the result of a further metamorphosis of it. This conversion of cellulose into gum has also been certified to by Kützing, by Hofmeister (*Berichte d. k. sachs. Gesellschaft d. Wissenschaft.*, 1858), by Nägeli (*Sitzungsberichte der k. bayerischen Akad. d. Wissenschaft.*, 1864), and by Cramer (Nägeli and Cramer's *Pflanzenphysiologie Untersuch.*, Heft iii.). It is, without any reasonable doubt, the only method in which gum is formed; and, as has been noted by the authorities mentioned, in the cactus, in the mistletoe, and in the fruit of various species of plants, probably all the mucilaginous vegetable principles are formed in this way. In the low algæ, during the formation of the motile reproductive bodies known as zoospores, the rapid conversion of the cellulose wall into a mucilaginous substance, soluble in water, always occurs.

THE HELIOPIKTOR.—In the *Berliner Klinische Wochenschrift* Dr. S. Th. Stein, of Frankfort-on-the-Main, gives a description of an instrument which he has invented, called the heliopiktor, by the use of which he claims that any one, although ignorant of the technicalities of photography, can obtain all the benefits of that art. No photographic atelier is needed; the plate upon which the impression is to be made is prepared automatically. The method possesses two principal advantages for physicians and surgeons over ordinary photography: 1. The plate is automatically prepared, so that any one ignorant of photography is able with the apparatus to produce good pictures. 2. The operation can be carried on in the light, so that a darkened chamber can be dispensed with as well as a photographic atelier specially arranged. The heliopiktor can be adjusted to the eye-piece of the microscope, so that pictures of objects under examination, magnified to any required degree, can be made. By means of special arrangement of mirrors, photographic pictures can be made of the various parts seen with the ophthalmoscope, laryngoscope, etc.

PUBLIC URINALS IN PARIS.—There are in Paris 730 places of public accommodation styled "urinoirs."

This number includes 40 having the shape of a kiosk, and belonging to the Compagnie des Kiosques, 234 of the same shape belonging to another company, and for each of which the city pays tribute; 228 having the shape of stalls or boxes lighted by gas, and about 200 having a central position, and three stalls on each side. The latter is the newest model, quite recently adopted. It is gratifying to know that the two uncovered slabs of slate so commonly met with at the angles of houses, and which exposed the occupiers to the gaze of passers-by, will be shortly entirely suppressed.—*The Lancet*.

EMULSION OF COD-LIVER OIL.—

R Ol. morrhue, f3viiij;
 Tragacanth., 3i;
 Sacchar. alb., 3iv;
 Ol. gaultheriæ, gtt. lx;
 " sassafras, gtt. l;
 " amygd. amar., gtt. x;
 Aquæ, f3viiij.

The tragacanth and sugar are to be dissolved in the water, and the mucilage strained. In this are to be incorporated first the essential oils and then the cod-liver oil. This makes an elegant-looking emulsion, not too thick, containing fifty per cent. of the oil, and of a rather pleasant taste and smell.—WILLIAM M. RICE, Jr., in *The American Journal of Pharmacy*.

RATIONAL MEDICINE WELL DEFINED.—The Italian journals relate that a vice-professor of the Faculty of Medicine of Naples, having asked permission of the Faculty to open a course on homœopathy, received the following answer: "The Faculty could not grant the authorization, seeing that rational medicine, which is taught on the basis of natural sciences, excludes allopathy as well as homœopathy, and, indeed, all absolute systems of medicine."—*The Lancet*, December 13.

THE INDIAN CINCHONA BARK.—At a late sale in London, part of a lot of mossed crown bark (*Cinchona officinalis*), the product of the plantations of the Neilgherry Hills, a range of mountains near the western coast of India, where the cinchona-tree has been for several years under cultivation, brought the great price of 5s. 9d. per pound. This is about \$1.40, gold rate. The whole amount disposed of on the occasion referred to was 23,646 pounds, at an average price of about seventy cents.

ACCORDING to the *Berliner Klinische Wochenschrift*, November 24, there is only about one-half the usual number of students at the various clinics of the city. The journal quoted attributes this falling-off chiefly to the very greatly increased cost of living in Berlin.

FOR THE CHAFING OF INFANTS.—Take of powdered starch two parts, white oxide of zinc one part. Make a fine, well-mixed powder. Dust the abraded parts with the powder, after proper cleansing.—*Exchange*.

THE death of Max Schultze, the celebrated anatomist, is stated to have occurred on the 16th ult., at Bonn.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—Your correspondent Vertex must, judging from his language, have had an exceedingly bad taste in his mouth when he wrote the letter which appears in your last number; but he seems to have grievances, and to wish them redressed. So far as can be gathered from his choice epithets, he objects, in common with the *Times*, to anything that may resemble advertising, except, perhaps, the name upon the window-shutter; and, moreover, seems to be particularly grieved that some people, who might fall to the share of struggling practitioners, endeavor to get free treatment at dispensaries and similar institutions. He is also opposed to hospital service in general: at least the size of his type and his elegance of expression favor that supposition. As, however, so far as I can judge, the weight of his article is intended to fall upon dispensaries, their physicians and patients, I should be glad of the opportunity of making a few remarks upon this part of his letter.

Now, considering that he, like the rest of us, is evidently anxious to get patients, it would seem, perhaps, injudicious to stigmatize that class of persons to which alone he thinks himself entitled to have access as "curs," "mongrels," and "whelps," all of low degree." It may be well enough to revile a poor patient, but to sneer at his position in society is, in a democratic country at least, injudicious. In fact, if he does it often I do not wonder much that there is a class "even from which he is debarred."

Most young physicians strive to obtain experience, believing that their future success must depend upon it; and hence arises, I believe, the desire to obtain dispensary and hospital positions. For I should like to ask Vertex whether he really believes that dispensary physicians increase their private practice while they are serving. I do not; and I fancy that the weight of the evidence is against Vertex. If a man lectures, and lectures well, he may obtain some consultation-practice, and from the very class which Vertex claims to represent; but as for ordinary practice, as Vertex says himself, so long as the patient can get advice from the dispensary doctor free, he is not inclined to pay any one for it; not even the man who is ready to give it to him for nothing. Afterwards, when experience has been acquired, practice does increase, no doubt; but, for the sake of humanity, Vertex might suppose that it is ability rather than charlatanism which has commanded success in the case of our leading practitioners. He should do so, or else, when his own success arouses the envy of future Vertexes, they may choose to consider it due less to his ability than to the suave manners and command of courtly language shadowed forth in his letter.

That lawyers, or even clergymen, do get paid, does not seem to me a convincing proof that medical men should not manage their own affairs as suits their own feelings; and the disparity seems removed when it is considered that, according to Vertex, while medical men do serve for nothing, it is for nothing,—save self-interest.

Medical opinions, it seems to me, have all the weight they are entitled to, from the condition of the medical art. Medical practice, as a rule, commands respect and obedience in proportion to its quality, and that quality can be improved only by experience,—an experience which can hardly be gained except by means of the dispensary system. That patients are taken away from some is, no doubt, true; and I freely admit that some persons well able to pay receive medical aid gratis, probably as much to the annoyance of the dispensary physician as of any other; but it seems to me as if there were rather the fault of the patient than of the physician; and while we all would be glad to see this class of persons forced to pay, it is hard to suggest a feasible remedy for the evil. Certainly Vertex does not do it, though, feeling so keenly as he does, it would be well if a little of his superfluous energy could be brought to bear upon the practical solution of the difficulty.

In conclusion, as I believe that the change must be made to some extent, at least among the patients, I may be pardoned for suggesting to Vertex that in writing to the daily press he should be less liberal in the use of such language as that which he seems to think appropriate when addressing the editor of the *Philadelphia Medical Times*.

Respectfully,

X.

PHILADELPHIA, February 8, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Will you permit me, through your valuable columns, to ask for professional opinions upon a matter in regard to which, unless I have held mistaken views, there is some laxity of practice in high places?

Mr. Greenbag, a lawyer of excellent professional and social standing, as been more or less constantly under my care for several years, on ac-

count of a tedious and troublesome, but not dangerous, malady. Some ten months ago, at his request, I called Dr. Bistoury to see him with me. After a most careful consultation, in which all the available plans of treatment were discussed, the course which I had been pursuing was decided to be the best, and I so informed Mr. Greenbag on the only subsequent occasion when I saw him professionally.

About two months ago, meeting Mr. Greenbag in the street, I was told by him that he was then, and had been almost ever since our consultation, under Dr. Bistoury's care for the same trouble. The treatment had been slightly changed, but no improvement had ensued.

Now, Mr. Editor, it seems to me that Dr. Bistoury's course towards me was neither friendly nor professionally correct. I had always regarded him as a man in whose honor I could implicitly trust,—as one whom I could call to the bedside of a patient without the risk of losing my own place there. Physicians would never call consultations if they were certain of being supplanted by those so summoned. And in proportion to the risk of it will they hesitate in so doing. If this is a legitimate thing,—if the consultant may quietly assume the charge of the case, and leave his friend and professional brother out in the cold, the former being without blame, and the latter without just cause of complaint,—the sooner we know it the better. Most assuredly I shall not give Dr. Bistoury another opportunity of "gobbling up" one of my patients, if I can help it; and yet I would rather have lost a dozen cases than have found out that my trust in him was misplaced.

If I am wrong in this matter, my own practice in regard to it has always been needlessly rigid, and I hope to be set right.

Respectfully yours,

SAMUEL SCALPEL.

January 23, 1874.

Answer.

THE relations of consultant and family physicians certainly involve many very delicate ethical questions. But we think consultants will find it most profitable to refuse to have anything to do with patients whom they have seen with their family physician. Whether this be so or not, in the present instance Dr. Bistoury seems to us to have been guilty of a clear infraction of Art. v. Sec. 4 of the Code of Ethics, which reads as follows:

"ART. v. SEC. 4.—A physician ought not to take charge of, or prescribe for, a patient who has recently been under the care of another member of the faculty in the same illness, except in cases of sudden emergency, or in consultation with the physician previously in attendance, or when the latter has relinquished the case, or been regularly notified that his services are no longer desired."

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

PERMIT me to express an opinion in regard to two or three points made by "Vertex" in your journal of February 7.

I heartily approve of the spirit of the first part of his communication. The SLIGHTS to which the younger members are subjected by a few of the older and established, yet grasping, members of our profession, are disgraceful, and come clearly within the jurisdiction of the Code of Ethics.

But "Vertex" makes a poor show in attempting to convince his readers that hospitals and such like institutions are "destined to crush not only the struggling practitioner, but to embarrass the whole profession."

Now, I take it that the history of medicine, past and present, justifies the assertion that our profession advances in intelligence, honor, and usefulness, and approaches nearer to a "fixed science," just in proportion as these said hospital facilities are increased.

Who are the men leading us out from the superstition, mystery, and errors of empiricism,—who are our investigators and communicators of advanced knowledge, but hospital men? Where could such an accumulation of reliable statistics be obtained, but in hospitals and dispensaries?

As in all other professions, ours owes its advancement in knowledge to the labors of a comparatively few of its members.

The hospital is almost invariably the field of their investigations.

The results become common property. We gather where they sowed.

Ex.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting will be held Wednesday evening, February 25, 1874, at 8 o'clock.

Dr. L. Turnbull will read a paper on "Tinnitus Aurium."

All regular practitioners of medicine in the city are cordially invited.

SATURDAY, FEBRUARY 28, 1874.

ORIGINAL COMMUNICATIONS.

THE USE OF ALCOHOL MEDICINALLY AND SOCIALLY.

BY GEORGE KERR, M.D.

IN treating this subject, I refer to the various substances in which alcohol is contained,—viz., brandy, whisky, wine, ale, beer, etc., and also spirits of wine as used in the various tinctures and medicinal preparations.

It is not my intention to speak of alcohol *per se*, but as used by the physician in the treatment of disease, and by individuals socially. Alcohol in its various forms until within a few years has been used by many in the profession as a cure-all.

Is alcohol a medicine? Here the question arises, What is a medicine? "A medicine is any substance, liquid or solid, that has the property of curing or mitigating disease in animals, or that is used for that purpose." The highest medical authorities are divided upon this question; some contend for its use, while others deny that it has any beneficial influence in disease.

Several years ago, in one or two cases I thought it had some good effect; but since, I have watched its action more closely, and without prejudice I have come to the conclusion that it is of little or no use as a medicinal agent. It has been said by some writers that where alcohol has been used in asthenic diseases there is no danger of the patient becoming fond of it. I cannot endorse this statement. A patient of mine with consumption, who was taking brandy, whisky, etc., by my advice, and also at the recommendation of other physicians, became so infatuated with it that she could not do without it, and was almost constantly intoxicated. This patient was over thirty years of age when it was first ordered, and had had no previous taste for it. A member of this Society informed me that a number of years ago he directed gin to be given to one of his patients for Bright's disease of the kidney: that patient is now a confirmed drunkard. She had no taste for liquors previously.

Most writers on low febrile disease assert and believe that alcoholic liquors are necessary,—yea, indispensable. Indeed, one would suppose, in reading the different writers in favor of the alcohol-treatment, that there is no disease which it does not benefit; that it is the *ne plus ultra*, the food and the medicine—the something which, if it does not cure, nothing else will do any good. On the other hand, we quote Dr. Henderson, of Shanghai, and Dr. Bishop, of Naples, in their reports of fever-treatment without stimulants, which reduced the mortality from twenty-eight to seven per cent. Dr. T. K. Chambers, physician to the Prince of Wales, who under the alcoholic treatment lost one patient in five, and under the non-alcoholic treatment had only three deaths in one hundred and twenty cases, said to his students, in his clinical lectures, "Above all

I would warn you against employing wine as a substitute for the true restorative treatment" (p. 61). The adherents of this remedy say that when solids cannot be taken into the stomach, it will take their place, acting as a tonic and supplying the necessary animal heat. Dr. Archibald Billing says,—

"Tonics give strength; stimulants call it forth. Stimulants excite action, but action is not strength: on the contrary, over-action increases exhaustion. One thing necessary to the recovery of the nervous system in fever is arterial blood. To produce this of good quality, digestion and free respiration are requisite. The digestion having been disturbed, it is useless to supply other than fluid nutriment—milk being the best—until some renewal of nervous energy takes place. This restoration will not be expedited by stimulants." (Principles of Medicine, fourth edition, London, 1841.)

Professor W. S. Gardiner, of the University of Glasgow, in some statistics published in 1864, says, in regard to the treatment of typhus fever in the hospitals in that city,—

"In many hundred cases (nearly 600) of all ages, the mortality lessened exactly as the dose of alcohol diminished; milk and buttermilk being given in its place. Wine, reduced from an average of thirty-four ounces to two and a half, was followed by a reduction of deaths from seventeen to eleven per cent. Of two hundred and nine children under fifteen years of age treated without any alcohol, not one died, though the very same class of cases treated with alcohol in the infirmary had a mortality of six per cent."

Professor Lehman, in his *Physiological Chemistry*, remarks that—

"When once the fact is admitted that the first thing in many diseases is to furnish a copious supply of oxygen to the blood, which has been loaded with imperfectly-decomposed substances, and to remove as quickly as possible the carbonic acid which has accumulated in it, these observations will have afforded us true remedial agencies which exceed almost every other in the certainty of their action. We should forbid the use of spirituous drinks, and not even prescribe tinctures which hinder the necessary excretion of carbonic acid." (Vol. iii., Respiration.)

Dr. Anstie, a stickler for the use of alcohol, remarks that—

"Alcohol cannot be scientifically administered until the urine of the patient has been analyzed and the sphygmograph has been applied for many hours; otherwise mischief, not benefit, will result; even the slight and trivial symptom of flushing in the face is a sign of the first degree of the poisonous action,—namely, a vaso-motor paralysis,—and shows that we at least have touched the border-line at which the beneficial action of alcohol ceases and its poisonous effects begin." (*Lancet*, January 25, 1868.)

Dr. Markham, F.R.S., says in the *British Medical Journal*, October 5, 1861,—

"It is scarcely possible to read fairly the works of the distinguished physiologists who have discussed this question, without feeling that they have been, spite of themselves as it were, driven, by their honest adhesion to the legitimate consequences flowing from their premises, to the conclusion that alcohol is unnecessary and injurious to the human system."

During the last six years I have almost entirely abandoned the use of alcoholic stimulants in my prac-

tice. I feel safe in saying that I have not prescribed a quart during that time. During this time I have had many cases of smallpox, typhoid, bilious, and other fevers, which were treated entirely without alcohol, and with very good results. I believe these cases recuperated much more rapidly than those in which formerly I had used it. Alcohol has a strong affinity for, and a peculiar effect upon, the brain; its first action being that of a spur, or more properly an irritant, it immediately afterwards produces a paralyzing effect upon the brain and nerve-centres. As constant dropping will wear away a stone, so will the constant use of alcohol, in disease or otherwise, benumb and pervert the whole nervous system. It does not cease here. The effects upon the circulation are equally powerful, and productive of the most direful consequences. The circulating fluid coursing through the body becomes impoverished, the blood-globules or disks are withered, the coloring-matter is extracted, the liquor sanguinis, which in health is of a bright pink hue, assumes a muddy appearance; all of which has been abundantly proved by Professors Carl Schultz, Munroe, Böcker, and Virchow. Dr. Gordon, of the London Hospital, stated before the Parliamentary Committee on drunkenness, "that seventy-five cases of disease out of every hundred could be traced to drinking; and whilst at Edinburgh most of the bodies of moderate drinkers he examined were found diseased in the liver."

Two hundred years B.C., it was written by a Jewish sect that intoxicating wine is *φάρμακον ἀφροσύνης*—"the physic of fools." I have taken the liberty to translate it, "the physic to make fools."

In view of the fact that alcohol is being used by many of the people too freely, and perhaps prescribed injudiciously by some of our profession, what are we as physicians doing to prevent its ravages? Are we standing in the breach, manfully assuming the responsibility which to a great extent must rest upon us? Or do we follow this mighty throng with a medicinal lash, called alcoholic stimulants, goading and hurrying them on over the frightful precipice, increasing largely the number of victims? While we may differ on the medicinal use of alcohol, we doubtless agree on its baneful social influence.

CURIOSITIES OF COUGH.

Reported to the Medical Library and Journal Association, December 12, 1873,

BY L. ELSBERG, M.D.,

Professor of Laryngoscopy and Diseases of the Throat in the University of New York.

(Concluded from page 293.)

VI—FREQUENTLY patients have come to me with another kind of cough, or hack, or hem, which almost invariably reveals its origin by its acoustic properties. I refer to an epiglottic hack. This no words can describe, but it is easily recognized by the practised ear. It is a very unsatisfactory cough to the patient, there being no, or but very little, expectoration. I will give an aggravated instance, and be brief in its recital.

A. A. B., æt. 57 years, naval officer, has for many years occasionally had a sore throat, being rather liable to catarrhal troubles. During the past year he has enjoyed remarkably good health and freedom from throat-disease, until he was seized five or six weeks ago with a cough which is perfectly tremendous in violence and sound. The intervals of rest never last over an hour at a time, and occur mainly in the middle of the day, while towards evening the paroxysms assume the height of severity. He says that for seventeen nights he has not slept: nevertheless, if it were not for his cough he would be perfectly well. He is naturally robust and very strong, and when he coughs he shakes the whole house he is in, and the cough can be heard, he thinks, half a block away. I found the whole upper edge of the epiglottis ulcerated.

An epiglottic cough may depend upon active hyperæmia, or varicose veins, or erosion or ulceration of greater or less duration and severity and of varying extent. The tickling of the throat and dry hack met with at the coming of cold or changeable weather very frequently depend upon some irritation at the upper edge of the epiglottis. Laughing, talking, swallowing, may aggravate it, though sometimes, by swallowing especially bland or thick syrupy liquids, or by dissolving astringent or sedative troches in the mouth, it is soothed. When the pathological condition has been recognized, the cure by mainly local treatment is usually easy, though sometimes tedious.

In all the preceding cases the character of the cough itself, particularly its sound, constituted the curious feature. But I could relate to you another series of coughs curious for other reasons. Of these I shall mention only one of the most curious, namely, the case of a lady whose husband had told me some years ago that his wife had a paroxysm of coughing whenever he had sexual intercourse with her. In the course of time these attacks became so severe that intercourse was almost given up. Living in the country, and enjoying otherwise excellent health, she had long refused to consult a physician, until I saw her last August. She presented the very picture of health, and could by no means be called "nervous,"—the common epithet to be applied to most women nowadays. Twenty-nine years old, she has been married eight years, and never has been *enceinte*. She has passed through measles, chicken-pox, croup, and whooping-cough before her twelfth year; has not had scarlet fever, or diphtheria, or any other sickness, since; her throat has never pained or troubled her otherwise than that at every menstrual period from the first, which occurred when she was twelve years old, a cough sets in a day or so before the catamenia appear, and usually lasts, with varying intensity, the whole period. She has always been regular, except, perhaps, two or three times in her life; then temporary amenorrhœa was due to imprudence in taking cold, and she remembers that the cough at these times was a great deal worse. I must not omit to state that her mother was afflicted in a similar way, though perhaps not so severely, and also an only sister, who died some years ago unmarried. After childhood until her marriage she does not remember ever to have had any cough except at the men-

strual period; since marriage, intercourse brings it on more violently than menstruation. I examined her throat, and could find nothing abnormal. She bore the presence of the laryngeal mirror in the fauces very well; the epiglottis presented no obstacle, and not only the whole of the larynx but also the trachea down to the bifurcation was brought into view. There was nowhere congestion or abnormal coloration.

I desired her to be examined by one of the gynecologists of this city, but she refused, and I consented to make a vaginal examination. No sooner had I introduced my finger, while she was standing upright, than the cough commenced, despite her strenuous efforts to repress it. There was no difficulty encountered in either super-sensitiveness or contraction; there was no spasm or abnormal secretion. I pressed upon the walls of the vagina, and touched and circumscribed the vaginal portion of the uterus, and the paroxysm of coughing became so violent that tears streamed from her eyes, her face flushed, she perspired freely, brought up some little phlegm, and became quite exhausted. I gave her some anodyne syrup that I had at hand, but it was fully half an hour before the paroxysm was over. She said that while I examined her, she felt a sensation of choking and irritation in the throat. On repeating the laryngoscopic examination, I found the vocal bands a little hyperæmic from the coughing,—nothing else. I then made her take about half an ounce of brandy, and chloroformed her, her husband assuring me that he had himself given her chloroform a number of times without any deleterious effect. Before she was quite under the influence, she again began to cough so that I thought she would have another paroxysm. When she was wholly insensible, I carefully examined the introitus and the whole vagina. There was no difficulty in introducing a large-sized speculum or a sound into the uterus; the os uteri looked to me of normal size and perfectly healthy; there was no leucorrhœa, no ulcer, no disease of any kind to be found, and of course there was now no cough.

So far as I know, this is quite a unique case. In a former paper on the connection of throat with other diseases, I pointed out especially the remarkable and inexplicable sympathy between throat disease and vaginal, uterine, and ovarian disease, and I might multiply instances in which I have observed cough reflected from the female generative organs; but in this case I could not ascertain the existence of disease of any kind: there was certainly no vaginismus or hyperæsthesia, and no hysteria. Then the seemingly hereditary factor of the affection is curious. When I suggested to the patient that there must be some abnormal condition of the sexual organs, as she, a healthy woman with a healthy husband, ought not to be childless, she justly pointed to her mother, who was affected with a similar cough and had borne five children.

I may on some future occasion continue the narration of cases of curious coughs. For the present, my object will be accomplished if by the recital of these I can bring out some observed by others; for while it is probable that I, as a specialist, have seen

more curious cases of cough than any one general practitioner, others may have met with curiosities of cough in their practice, which it would be of great interest to have brought to the knowledge of the whole profession.

CORNEAL WART.*

BY C. A. ROBERTSON, M.D.,

Member of the American Ophthalmological Society; Ophthalmic and Aural Surgeon at St. Peter's Hospital, Albany, and at the Troy Hospital.

THIS case presents features of much interest, both to the profession and to the patient,—to the former for its instructiveness, and to the latter not merely for a fortunate escape from a dreadful and uncalled-for mutilation, but also for the restoration of sight to a blind eye.

The patient, named James Taylor, by occupation until recently a grocer, was about seventy years old. He had been afflicted for several years with a dermoid growth, or *wart*, which started on the outer and lower part of the right eyeball and early showed a tendency to intrude upon the transparent cornea. The patient called on me several times at an early period of his complaint, and I attempted to destroy the wart by cutting off its surface and then applying chromic acid. This treatment not proving successful, or for some other cause, he ceased his visits, and I lost sight of him entirely until he presented himself at the ophthalmic clinic at St. Peter's Hospital in October last.

My friend Dr. James L. Babcock, of this city, then advised that he should consult me, because he had learned that an opinion had been given at a certain medical institution that the growth on the eyeball was of a dangerous character, and that "the tumor" would grow until it became as large as his fist! The only thing to be done, said the sapient "oculist," was to "remove the eyeball." This being cut out of his head, of course "the tumor" would at the same time disappear!

Upon examination, I recognized my old *verrucous* acquaintance, only somewhat enlarged. In its growth the wart had confined itself within the limits of the cornea, which it entirely covered, except a very narrow tract at the upper inner margin. As it so completely covered the front of the eye, all sense of vision was, of course, obliterated.

In appearance the wart presented a roundish form and a whitish-gray color. To the touch it was soft and unctuous. In structure it was composed of papillæ, which were separable almost to the base; and near the lower edge these papillæ stood up in coarse filaments, or little crowded columns, almost a quarter of an inch high. From this they were graduated down until they were nearly on a level with the cornea at the region of most recent invasion.

In order effectually to rid my patient of this somewhat formidable wart, the eyelids were first held apart with the ordinary silver-wire speculum, and then, with delicate scissors curved on the flat, all the coarser portions which it was practicable to

* From a paper presented to the Medical Society of the State of New York.

cut were removed, leaving on the eye only the base of the structure as a raw surface. Then, taking a bent lance-shaped knife (*iridectome*), I carefully insinuated its edges under the upper sessile border of the excrescence, and, by gentle manipulation, teased away the adventitious growth from its connection with the surface of the cornea. When the operation was terminated, the color of the iris and the black pupil were visible, and the patient remarked that he could see objects in the room.

Very little reaction followed. The cornea steadily improved in clearness as the natural superficial or epithelial layer was reproduced, and within a very few weeks the sight became as good as in the other eye, in which the sight was perfect.

The last time I saw the patient was four months after the operation. There was no vestige of the old trouble to be seen, and the cure appeared to be perfect.

OPERATION ON FISTULA IN ANO WITH THE ELASTIC LIGATURE.

BY H. S. SCHELL, M.D.

THE elastic ligature which has lately been brought before the notice of the profession in connection with the removal of tumors and other operations, seems to have special adaptation to the cure of fistula in ano.

Every one knows how troublesome to the surgeon is the hemorrhage which is apt to follow the ordinary operation by the knife, and how irksome to the patient is the confinement to bed and the artificially-induced constipation which it is usually considered necessary to enforce.

I endeavored to obviate these difficulties by the employment of the elastic ligature in the case of a man, Michael D., aged 36, on whom I operated on the 9th ult., at St. Mary's Hospital.

The fistula, which had existed for several years, was of small extent, opening in the skin about half an inch from the verge of the anus, and within the bowel somewhat over an inch from its termination, embracing indeed but little more than the external sphincter ani.

The ligature was drawn through the fistula by means of an ordinary eyed probe, such as is found in every pocket-case of instruments, brought down outside the rectum, and tied pretty tightly.

An opium suppository was prescribed, to be used in case any pain followed the constriction of the parts. The suppository was not asked for, however, by the patient, who stated that he had no pain at all, and who went about the ward as long as he remained in it, assisting the nurse in the care of the other patients.

The ligature came away at stool on the fourth day, leaving a granulating wound, to which no further attention was paid, except as to cleanliness, and which healed in the usual manner.

So far as this case is concerned, therefore, the advantages to be derived from the employment of the elastic ligature in this operation appear to consist in—

1. The entire freedom from pain.
2. The avoidance of annoying hemorrhage.
3. There is no need of confinement to bed.
4. The bowels may be left to their ordinary regular habits.

The ligature used in this instance was of the kind employed by ladies for toilet purposes, and may be obtained at any trimming-store.

The best is composed of three strands of caoutchouc somewhat compressed within a plaited envelope of white silk into a round cord, and has the strength of an ordinary ligature.

In purchasing, the quality of the article may be judged by smartly stretching an inch or so several times; when, if unreliable, the gum will crack in various places and slightly project between the threads of the silk, giving the cord a rough, half-broken appearance. A good article has a soft, elastic feel, while the bad is hard and stiff.

It is better not to keep much on hand at a time, as the gum finally becomes hard and brittle.

NOTES OF HOSPITAL PRACTICE.

BELLEVUE HOSPITAL, NEW YORK.

Reported by F. W. CHAPIN, M.D.

TWO CASES OF ICTERUS.

CASE I.—Mary Q., æt. 70, domestic. Admitted November 27, 1873. Patient thinks her mother died of phthisis; her father "died of a sore leg," the sore beginning at the toe and extending over the foot and leg to the knee. Patient herself always enjoyed good health till ten years ago, when she strained herself while helping to carry a heavy stove up-stairs. The woman who was assisting her let the whole weight of the stove come upon her, so that she was obliged to put forth all her strength to save herself from falling. She says she felt stupid for two days after this, sleeping most of the time. Then her right arm and shoulder began to swell up, and became very painful. She was unable to raise the arm, and it was a year before she regained the use of it. Since then she has always had a pain in the right side, like a "stitch," whenever she has made any bodily exertion. Since the injury, she has been troubled with swelling of the limbs and the abdomen; and at one time, three or four years ago, her water was scanty in quantity. She has always been feeble since the injury, and unable to do much work.

One week before admission she began to have a feeling of heaviness in the head, and was sick at the stomach. In the evening of the day on which these symptoms occurred she was taken with severe pains across the loins and in the back, and her abdomen began to swell. These symptoms went away after the lapse of three days, leaving her very feverish.

From that time till admission—a space of four days—she had chills every night, followed by an increase of the fever.

On admission, patient is a well-nourished woman, quite markedly jaundiced. She does not know when the jaundice came on, as she has been living in dark apartments. She complains of slight pain in the right side. Urine is high-colored. Chemical and microscopic examination negative. Fæces are of dark-yellow color.

Liver extends to free borders of ribs, and two and a half inches to left of median line. No tenderness in this region.

Spleen normal in size.
Heart and lungs normal.
 November 28.—Jaundice increased. Slight flush of cheeks.
 November 29, A.M.—Temp. 100°; P.M., temp. 99°.
 November 30.—Patient was very thirsty and slightly delirious during the night.
 December 1, A.M.—Temp. 99½°.
Physical examination of chest negative.
 December 3, A.M.—Pulse 84; resp. 20; temp. 99¾°.
 Patient passed a very restless night; had chills and fever, alternating during the entire night. Had no pain, no headache; no nausea; eyesight as good as ever.
 P.M.—Pulse 98; resp. 24; temp. 102¼°.
 December 4, A.M.—Pulse 80; resp. 24; temp. 100¾°.
 " " P.M. " 88 " 36 " 102½°.
 " 5, A.M. " 88 " 24 " 100¾°.
 Patient's fæces are slate-colored.
 December 13, A.M.—Pulse 68; resp. 32; temp. 100°.
 " " P.M. " 88 " 36 " 102°.
 Cough troublesome, especially at night. Physical examination reveals evidences of bronchitis.
 December 16, A.M.—Pulse 68; resp. 24; temp. 99¾°.
 " " P.M. " 80 " 22 " 102°.
 Some desquamation of the cuticle on the hands, and the jaundice seems to have faded slightly.
 December 17, A.M.—Pulse 72; resp. 28; temp. 99°.
 Jaundice appears more marked.
 P.M.—Pulse 84; resp. 30; temp. 100½°.
 December 18, A.M.—Pulse 68; resp. 24; temp. 99½°.
 Small amount of bile in the fæces.
 December 20, A.M.—Pulse 72; resp. 22; temp. 100½°.
 " " P.M. " 84 " 30 " 100½°.
 Patient feels weak; cough very troublesome.
 December 22, A.M.—Pulse 66; resp. 27; temp. 99°.
 " " P.M. " 78 " 24 " 100½°.
 " 23, A.M. " 76 " 22 " 99½°.
 Patient's fæces this morning are of normal color, evidently bile-stained.
 December 24, A.M.—Pulse 76; resp. 24; temp. 99½°.
 December 26.—Fæces continue to be of normal color. They have been examined daily since they first became clay-colored, with a view to the discovery of biliary calculi; not one has yet been found. Patient still suffers from bronchitis; jaundice less marked.
 December 27, A.M.—Pulse 72; resp. 22; temp. 99½°.
 Jaundice markedly less. Patient vomited some greenish matter last night. A small calculus of cholesterolin was this morning found in the fæces; it had several facets, and was about one-eighth of an inch in diameter.
 P.M.—Pulse 84; resp. 24; temp. 100½°.
 December 29, A.M.—Pulse 72; resp. 22; temp. 100°.
 Patient quite comfortable; complains only of cough; expectoration quite abundant; jaundice fast disappearing.
 P.M.—Pulse 76; resp. 26; temp. 101°.
 December 30, A.M.—Pulse 72; resp. 20; temp. 99°.
 Three small calculi of cholesterolin were found in the fæces, faceted like the first.
 January 4, A.M.—Pulse 86; resp. 22; temp. 100°.
 Patient suffers from nausea; jaundice slightly increased.
 January 5, A.M.—Pulse 76; resp. 24; temp. 100°.
 Patient comfortable; no nausea; considerable cough.
 P.M.—Pulse 80; resp. 20; temp. 101°.
 January 6, A.M.—Pulse 80; resp. 24; temp. 99¾°.
 " " P.M. " 80 " 20 " 101°.
 " 7, A.M. " 86 " 24 " 101°.
 Patient coughs much; spits a greenish-brown, frothy matter; jaundice slight.
Physical examination of lungs shows dulness and feeble respiration over lower half of right lung, posteriorly.
 P.M.—Pulse 96; resp. 28; temp. 102°.

January 8, A.M.—Pulse 88; resp. 24; temp. 100½°.
 " " P.M. " 88 " 24 " 101¼°.
 " 9, A.M. " 100 " 20 " 100½°.

Patient expectorates a dark, yellowish-brown matter; crepitant râles; bronchial breathing and bronchophony over upper third of right lower lobe, posteriorly.

January 12.—Patient died.

Autopsy, thirty-eight hours after death.

Brain normal.

Lungs.—Gray hepatization of lower lobe of right lung; red hepatization of portion of upper lobe of left lung.

Heart normal.

Abdomen.—The peritoneal sac contained a large amount of flocculent serum.

Liver.—Left lobe of usual size, but tilted upwards by tympanitic condition of transverse colon. Right lobe a little smaller than the average.

Tissue.—Section shows bile-ducts in many places dilated to size of portal vein in same canal, and containing a thick mixture of bile and muco-pus. The centre of the lobules bile-stained.

Gall-bladder.—Small walls thickened and adherent to the duodenum and the transverse colon; contains two calculi of the size of marbles, faceted, and twenty-eight small ones, of the size of little peas, and also having facets. Color of these is white, except a little yellow in the centre; composition, cholesterolin, with a little bile-pigment.

The cystic duct was dilated so as to admit the little finger. The common duct and the hepatic duct were capable of holding the index-finger.

The common and cystic ducts contained twenty-two calculi, similar in appearance and structure to those in the gall-bladder. Two of these were large, slightly exceeding in size the two large ones which were found in the gall-bladder.

There was abundant evidence of catarrhal inflammation of the gall-bladder and ducts.

Spleen slightly enlarged. Capsule thickened in one portion.

Kidneys large, of deep-yellowish color, mottled with whitish spots.

Stomach and intestines appeared normal. The opening of the common duct in the duodenum was a trifle larger than usual; and just back of it was a small calculus.

The inflammatory condition of the gall-bladder and ducts above alluded to was considered sufficient to account for the high and irregular temperature, which, together with the apparent decrease in the size of the liver, seemed, early in the patient's illness, to point to acute yellow atrophy as the correct diagnosis.

Case II.—Emily B., æt. 31, intemperate, admitted December 29, 1873. Patient deeply jaundiced on admission; has been drinking hard for a week; has been in the hospital before for a similar illness after drinking; mind is clear; great thirst; liver somewhat enlarged.

P.M.—Pulse 116; resp. 34; temp. 102¼°.

December 30.—Patient about the same.

A.M.—Pulse 112; resp. 32; temp. 102°.

P.M. " 136 " 28 " 101°.

December 31, A.M.—Pulse 112; resp. 28; temp. 101°.

Patient slightly delirious; great thirst; mouth dry; tongue coated brown on upper surface; under surface and edges red; excessive jaundice.

December 31, P.M.—Pulse 120; resp. 32; temp. 101¾°.

January 1, A.M.—Pulse 120; resp. 40; temp. 101°.

" " P.M. " 126 " 42 " 101°.

Urine contains bile and abundance of albumen; reaction acid; patient has been stupid all day.

January 2, A.M.—Pulse 144; resp. 36; temp. 100°.

Patient unconscious; cannot be aroused to answer questions; lies with her mouth half open.

P.M.—Pulse 136; resp. 24; temp. 101½°.

Liver of same size as on admission.

January 3, A.M.—Pulse 144; resp. 56; temp. 103°.

" " P.M. " 144 " 56 " 103¾°.

Patient still unconscious; cannot be roused. Dr. Clark thinks she is suffering from meningitis, and that the jaundice is "an accident."

January 3, 11 P.M.—Dead.

Autopsy.—*Exterior.*—Deep jaundice; rigor mortis well marked.

Brain.—On the inner surface of the dura mater a recent exudation, fibrinous, and also an older, though comparatively recent, vascular membrane in which vessels are apparent; also, a few small recent hemorrhages.

Brain and its vessels appeared normal, save the yellow tinge to the serum as it oozed from the cut vessels.

Heart normal.

Lungs.—Small hemorrhages in the lower lobe of the right.

Liver.—One-half larger than normal; surface granular.

Section.—Marked increase of connective tissue around small spaces of lobules; tissue of lobules yellow from fat and bile; bile-ducts contained mucus and bile; gall-bladder large, contained a thin bile, and sand-like pigment concretions.

Spleen.—One-half larger than normal.

Stomach.—Catarrh.

Duodenum.—The opening of the bile-duct plugged up by a small mass of mucus; the duodenal extremity of this plug was colorless, while the end nearer the gall-bladder was bile-stained.

On removing this plug the bile flowed readily. The intestinal contents were bile-stained.

Kidneys bile-stained.

Dr. Janeway, who made the autopsy, considered death due to cholæmia, and that the brain-lesion had very little, if anything, to do with the symptoms.

EPISCOPAL HOSPITAL.

SERVICE OF DR. WHARTON SINKLER.

Reported by Dr. JAMES C. REA, Resident Physician.

CASE OF TYPHOID FEVER IN A CHILD, COMPLICATED BY INTESINAL HEMORRHAGE.

MARY T., æt. 8 years, was brought to the hospital September 17, 1873, by her mother, who left her without giving any account of her sickness. The following history was obtained two days later. For ten days previous to her admission the patient had been sick. It was noticed that she had lost her appetite, and that she was listless, and disinclined to play or move about. At the same time she began to complain of pain in her back and limbs, which was followed by diarrhœa and abdominal pain. For four or five days before coming into the hospital she had had from three to six small, slimy stools a day. At night her skin was hot, and for several nights she was flighty and wandering in her mind, without having had at any time active delirium. She had a dread of being left alone, and in the night would occasionally jump out of bed in a fright. She lost flesh and strength rapidly. On admission, the child was much emaciated, and was so weak as not to attempt to move in bed. She utterly refused to answer a question, and lay with an expressionless and rather dejected countenance, and dull eyes. Her skin was dry and shrivelled, and of a dirty-brownish color. Tongue lightly coated, but moist. There seemed to be very slight tenderness diffused generally over the abdomen. She had no appetite, and there was diarrhœa, the stools being watery, and

of a brown color. There was but little fever. Was given spt. æth. nit., and liq. amm. acetat., aa f3ss every four hours; whisky, f3i in milk every four hours, and beef-tea. At 10 P.M. she was sleeping quietly.

At 2 A.M. on the 18th the patient was found to have had a passage from the bowels of about eight ounces of almost pure blood, partly clotted and part still liquid. Acid. tannic. gr. iii, in glycerin f3i, every fifteen minutes, was prescribed. In about a quarter of an hour after the first hemorrhage she had a second, and in this she was seen to pass the blood clotted with some fecal matter intermixed. The amount of blood lost in all was almost a pint.

There was no abdominal tenderness or tympanitis, but the patient's face and extremities became icy cold, and her prostration was excessive. After two doses of tannic acid had been administered, gallic acid was given in doses of grs. v every fifteen minutes, until grs. xx had been taken, when it was given every three hours. At the same time a heater was applied to the feet, and whisky f3i in hot milk was administered every three hours, and hot beef-tea at the same intervals. In an hour she reacted, the extremities became warm, and she fell asleep.

The next day she seemed comfortable, and there was no pain on pressure over the abdomen. In the absence of any previous history of the case, and there being no fever or intestinal pain, it was extremely puzzling to know what had been the origin of the hemorrhage. Dr. Sinkler, thinking it might possibly have arisen from a polypus or an ulcer of the rectum, passed his finger into the bowel and carefully explored it; but the examination gave rise to no pain, and no polypus, fissure, or ulcer could be detected. The question of intussusception of the bowel was also considered; but the absence of pain made this condition unlikely, and no tumor could be detected on palpating the abdomen.

The fever-mixture was discontinued, and quiniæ sulph., gr. ss, with tr. ferri chlor., gtt. iv, in honey f3i, was ordered to be given three times daily. Beef-tea, milk, and whisky to be continued.

September 19.—The patient had yesterday evening a stool with no traces of blood in it. She was quiet, free from fever and pain, and took whatever was given to her, but still would not speak.

The condition of the child varied but little after this time from day to day. Her temperature was taken, and found to be normal. On the 26th, in the morning the temperature was 98°, pulse 96; evening, temperature 98°; pulse 92.

September 27.—Morning, temperature 98½°, pulse 98; evening, temperature 98¼°, pulse 96.

September 28.—Morning, temperature 98½°, pulse 100; evening, temperature 98½°, pulse 100.

September 29.—Morning, temperature 98½°, pulse 100; evening, temperature 98½°, pulse 104. The diarrhœa still continued; three or four small, yellowish stools daily. The iron and quinine were stopped, and acid. hydrochloric. dil., gtt. iv, every four hours, ordered.

October 1.—Dr. Norris took charge of the ward.

No change in the case was observed until October 5, when there was a sudden rise in the temperature. In the morning the temperature was 99°, pulse 116; evening, temperature 103°, pulse 108. There was nothing to account for this sudden and great accession of fever.

October 6.—Morning, temperature 102½°, pulse 142; evening, temperature 103°, pulse 108. She was much prostrated, and was therefore given whisky f3i every two hours, and quinine gr. i every six hours.

October 7.—Morning, temperature 102°, pulse 120; evening, temperature 103°, pulse 120.

October 8.—Morning, temperature 100°, pulse 112; evening, temperature 102°, pulse 120.

The temperature steadily fell from this time, and on

the 12th in the morning it was as low as 97°. In the evening it was 98½°. As the diarrhœa continued, bismuth, subnit. gr. x and morph. sulph. gr. ʒi, three times a day, were prescribed; and instead of the quinine, as ordered on the 6th, tinct. ferri chlor. gtt. iv, and quin. sulph. gr. ʒi, were given three times a day.

October 20.—Diarrhœa better. Two stools a day, of better consistency and more natural color.

November 4.—The patient was out of bed; had a desire for food, and was gaining strength rapidly. The diarrhœa had ceased, and she had a clear, healthy color of skin.

Discharged well November 25.

REMARKS.—The point of interest in this case was the hemorrhage which took place on about the eleventh day from the beginning of the sickness, and its being unaccompanied by any signs of pain or inflammatory action at the time of its occurrence, only a few hours after the patient's admission. The nature of the malady had not then manifested itself, but the subsequent course of the case made it clear that it was one of typhoid fever. The diarrhœa, hebetude, low delirium at times, and the long, tedious illness, together with the variations in the temperature, as shown in carefully-prepared charts, which are, unfortunately, too long to be inserted here, all point to that disease.

It is true that no rose-colored spots were seen, and that there was no meteorism; but these phenomena are not invariable accompaniments of this disease. In seven out of thirty cases observed by Hillier* there was no eruption.

Intestinal hemorrhage is not a common accident in the typhoid fever of children. Vogel† says that it and intestinal perforation are "exceedingly rare." Churchill‡ makes the same assertion, adding that M. Barrier mentions but one instance in two hundred cases. Aitken§ also states that this accident is very unusual in children. On the other hand, Hillier|| asserts that he met with it in four out of thirty cases, and Ellis¶ gives twenty-five per cent. as the proportion of cases in which hemorrhage occurs.

Another point worthy of remark is that the hemorrhage should have happened at a time when the child seemed but slightly ill, and that no severe symptoms should have set in until several days after its occurrence. Dr. Hillier remarks that although intestinal hemorrhage is generally a grave symptom, he has seen it occur in "comparatively mild cases that went on well."

TRANSLATIONS.

ABSTRACT OF A CLINICAL LECTURE ON THE EVOLUTION OF SYPHILIS.

From the French of Dr. AL. FOURNIER.**

GENTLEMEN,—As a result of actual experiment as well as a consequence of sound clinical observation, it is established to-day, and that quite definitely, that syphilis, with man at least, obeys in its evolution and general development certain fixed rules, to which, without claiming too much, we may give the name of laws.

These laws, if you will permit me to call them such,

I shall endeavor to formulate for you in the present lecture, and to justify them in your eyes by a systematic discussion.

They are as follows:

1. Syphilis is never generated spontaneously. It is always the result of a *contagion*, of an inoculation, of the material penetration into the organism of a special virulent substance.

2. The first appreciable phenomenon which results from this contagion only manifests itself after a greater or less lapse of time, constituting a true incubation.

3. The first appreciable phenomenon which results from the contagion or the artificial introduction of virulent matter into the organism manifests itself always *in the exact spot* where this matter has penetrated; in this spot and not elsewhere.

4. The primary lesion, the resultant *in situ* of the contagion, always remains isolated and solitary for a certain time, during which it constitutes or appears to constitute the only expression by which the disease is manifested.

5. It is only later that this apparently local lesion is succeeded by the manifestation of other symptoms of a multiple and varied kind, which differ essentially from the local affection in that *they are no longer localised, like it, at the point where contagion took place*, but are disseminated in all directions, spread through the entire system and susceptible of affecting all the tissues, all the organs.

Expressed thus in a dogmatic and abstract manner, these laws may seem to you obscure on certain points. A few comments will make them more clear.

Now, as to the first law. It is certain, gentlemen, that at some period in the past there must have been a syphilitic individual who did not contract the disease from some one else. How this has happened we have no idea; but one thing is no less positive, which is, that to-day such a thing does not take place, and the following proposition may be regarded as an axiom: *Whenever syphilis is acquired, it is because it has been taken from some one.*

Syphilis, in fact, in our day is not the result of individual morbid causes; it is not primarily elaborated in the economy; it is not the result of latent predisposition, of functional excess, of wearing-out organs, of deteriorating systems, of constitutional taints elaborating themselves slowly and secretly in the organism. It does not attack the patient like a pulmonary tuberculosis or a cerebral hemorrhage. No: it is always and in all cases the result of an accidental event, of an external cause, the effect of contagion.

This is beyond doubt: daily experience confirms the point, and it would be superfluous to insist upon it. But it is this, simply, gentlemen, which explains our first law.

Our second is equally simple in its meaning. Putting it into other words, we may say that a person exposed to contagion does not immediately feel the effect, but only after a more or less considerable period of time.

Take, for example, an individual exposed to contagion on the first of January, and who becomes on that day infected. Does he present immediately the first symptoms of the disease? Not at all. Will he present such symptoms on the second, the third, the fifth of January? Examine the genital organs at this time, and you will find them perfectly healthy. Will it be on the seventh or eighth? No more so. It is only much later—the fifteenth, twentieth, thirtieth of January, or possibly even subsequently—that you will perceive a morbid *something*, which in a few days becomes an evident lesion, the first sensible indication of the disease,—the "*primary lesion*" or "*chancere*."

Now, here we have a certain space of time separating the moment of contagion from that at which the

|| Loc. cit.

¶ Diseases of Children, Philadelphia, 1873, p. 88.

** Leçons sur la Syphilis, Paris, 1873.

first symptom of disease shows itself; it is this lapse of time to which the name "*incubation*" is given.

That this incubation is real and constant I can prove to you both by the results of experiment and by those of clinical observation.

Consult the facts of experimental syphilis; they will afford you the exact truth on this subject,—the result of the most strict and rigorous observation. For, by this means, the hour, even the instant, at which the virulent matter was introduced into the organism has been plainly determined, as well as the hour—the very instant, almost—when the earliest morbid phenomena first made their appearance.

Well, what do they teach us? This: that always and in all cases a more or less considerable space of time elapses between the moment of inoculation and that at which the primary lesion first shows itself.

But what is this lapse of time exactly? Observe the figures. In a single case 10 days, and in the others 15, 17, 18, 20, 21, 23, 25, 25, 27, 28, 28, 28, 29, 34, 35, 39, 42 days, which gives a mean of about 25 days.

Never, never, I insist designedly, does the primary lesion appear immediately, or the next day, or the day after, or the third or fourth from the inoculation, or even during the first week.

Now and then, indeed, some local phenomena are produced as the result of the abrasion of the skin or the introduction under it of a virulent foreign liquid; but these traumatic accidents are rapidly effaced, and it is only later that the earliest syphilitic lesion makes its appearance, after a more or less prolonged period of quiet elaboration. All observations, I repeat once more, agree on this point.

What have we here, then, gentlemen, but a mathematically-demonstrated truth?

This demonstration having been made by the irrefutable data of experiment, let us now consult those of clinical contagion.

A certain time always elapses subsequent to this contagion during which *nothing is produced*; during which the future subject of syphilis may imagine himself unharmed. This period, you will particularly notice, has the same duration as in experimental syphilis. Like the latter, it may vary in individuals, but the *mean* is the same. That is to say, this period, sometimes so short as ten or twelve days, may attain in other cases a duration of twenty, thirty, even forty days. Here, as in all virulent affections, there are unknown conditions which increase or diminish the length of incubation.

But the mean *habitual* duration is, as in the case of artificial incubation, from three to four weeks.

It is not, then, until three or four weeks after exposure to contagion that the patient observes the appearance of the primary lesion—the chancre—on his person.

Observe, then, an undoubted and very interesting fact, from which a precept may be derived that I must not fail to make you acquainted with. Frequently you will be consulted by patients who, having doubts of an adventurous coition, come to be examined by you and to obtain a clean bill of health. This is, for example, the constant history of persons from the country, who, having committed some peccadilloes in the city, hasten to a physician on the eve of their departure to know if they have anything to fear, and if they can return with all confidence to the conjugal couch.

Consulted under such circumstances, I shall suppose you to examine your patient, and to find nothing upon him. He is, at least to all appearance, perfectly sound. This fact established, what are you to say to him? Will you reassure him absolutely—give him a clean diploma? To do so, gentlemen, would be a grave fault, a culpable dereliction, which might have the most deplorable results. For, strong in your assurance, the

said consultant returns home, believing himself safe from all danger; and if, some weeks later, a slight lesion—as chancre always appears slight at first—manifests itself on his person, he takes it for an insignificant erosion, a herpes,—in fact, as something of no moment, and non-contagious, and, in consequence, exposes himself to communicate it. In this manner, doubt not, is the syphilitic contagion often transmitted in marriage. I have seen many such cases; it is the same story,—the evil done, the contagion transmitted, and lamentations on the part of the husband. "How could I have anticipated such a thing? I had not seen a woman for three, four, or six weeks. I had taken pains to have myself examined by a physician before my departure from the city, who told me *that I had nothing*,—that I was perfectly sound. It is this physician who is to blame, and not I; if he had warned me I should not have given the pox to my wife."

Do not founder upon this reef, gentlemen. Consulted in a similar case,—and you will be often,—know how to reply as you should reply, and as your knowledge of the incubation of the disease will alone permit you to reply, and say to your patient, "Yes, at present you have nothing. But syphilitic lesions show themselves *tardily*,—many weeks after contagion. Accordingly, do not believe yourself perfectly safe; observe, and if the least phenomenon, *however slight it may be*, should manifest itself, abstain, for there will be danger of contagion."

This reply will, perhaps, not be to the taste of your patient, but it will be dictated by prudence, it will be justified by a sound knowledge of the disease. And, guarding your responsibility thus, you will prevent more than once, you may be sure, the most regrettable accidents.

One word more to complete the history of the syphilitic incubation. Its duration may certainly extend beyond the average already indicated as most common. It is *often* as long as thirty days, and sometimes goes even to forty. I think I have even observed a case where it has reached two months and a half!

Putting aside extraordinary cases, we may say that now and then the incubation attains a limit varying from thirty to forty days, which is very great compared to the duration generally ascribed to it, and in flagrant contradiction to the views held some years ago by the highest authorities.

Our third law is very important, clinically. It expresses, in other words, what M. Ricord used to say, wittily: "In catching the pox, one is punished first just where one has sinned." If the penis alone is exposed, it is the penis alone that is attacked; if one is exposed by the mouth or the anus, it is at the mouth or the anus that the initial lesion is manifested.

Nurses, for example, are exposed through the breast: it is there that they frequently become affected. It is the same in other cases which it would be superfluous to cite; it is a fact of daily observation.

Experimental inoculations give the same result. Wherever the inoculation has been practised, there the first morbid phenomena are produced; always there, there only, and nowhere else.

Observe, then, gentlemen, one more truth, which I give you as demonstrated beyond all dispute.

In our fourth law we have again clinical and experimental facts concurring mutually in the establishment of a truth.

Let us take a patient who has contracted syphilis quite recently,—say a fortnight ago. What will he present? A lesion, a chancre, at the point where contagion took place. And what else? Nothing, absolutely nothing else. He has a chancre, and that is all. Examine him from head to foot; auscult him, percuss him, interrogate all his functions, and you will find

nothing else of a pathological nature about him. The chancre appears to constitute in itself alone the whole disease,* and were it not for our experience we might imagine that this patient would escape ulterior manifestations. Experimental observations give a like result.

Here, then, is an absolute rule. The local lesion of either contagion or inoculation remains during a certain period the only phenomenon by which the disease expresses itself. This period is usually from several weeks to forty-five days. But, this period passed, the aspect of things changes, and the disease tends to become generalized, as has been stated in our fifth law. After a delay of some weeks, then, we perceive certain manifestations, varied in form and seat, joined to the local lesion of contagion. Such are erosions or ulcerations of the buccal, vulvar, or anal mucous membranes, pains in the joints, limbs, etc., various lesions of the tendons, the muscles, or the periosteum, falling of the hair, and a hundred other phenomena, which I shall describe to you at another time. These new lesions, however they may differ in other respects, have all one character in common. They all differ from the primary lesion in this, that *they are not, like it, localized at the point where the contagion took place*. Far from it. The whole body seems to be their domain, and their multiplicity is only equalled by their infinite variety of forms and expressions. Affecting, or having power to affect, all the tissues and every organ, they seem to testify by their freedom of expansion a sort of generalization of the disease throughout the entire economy,—a saturation of the whole system by an infectious principle, by a morbid influence everywhere present.

To sum up, it has the power of reproducing itself everywhere, while the initial lesion has only the faculty of reproducing itself at one point. Therefore, to distinguish these later lesions from the primary one, the name has long been given them of general lesions.

Such, gentlemen, are the laws to which, in man at least, the evolution of syphilis is subject from its origin.

These laws I present you as certain, as absolute, as definitive; for they rest on the one hand upon most rigid clinical observation, and on the other upon the incontestable and undisputed facts of experiment.

A. VAN HARLINGEN, M.D.

TRANSFUSION WITH THE BLOOD OF DIFFERENT ANIMALS.

IN a recent number of the *Berliner Centralblatt*, Dr. Landois gives an account of a number of experiments performed by himself with a view to ascertaining the effects produced by transfusion or admixture of heterogeneous kinds of blood.

The blood of various mammals was injected into the veins of the frog, when it was found that within a very few moments disintegration of the mammalian corpuscles began. The length of time which was required for entire disintegration varied greatly with different animals. Thus, the corpuscles of the rabbit became dissolved in from two to five minutes, while others resisted for a greater length of time, those of the pigeon not disappearing for eighty minutes.

Under the microscope the corpuscles were seen to change in the clear frog's serum, becoming crenated and displaying active molecular movements. In a short time they became quite globular, and seemed decreased in size. Afterwards they became paler and paler, and later still only the stromata remained, which also finally disappeared.

* I do not speak here of bubo, which is, so to speak, merely an appendix of chancre.

When mammalian and frog's blood were mixed in a test-glass, the stromata of the dissolved blood-corpuscles showed a tendency to collect in masses. A certain paralysis of the lower extremities noticed in some of the animals experimented upon by Dr. Landois may, he thinks, be due to emboli formed in this way.

That fibrin may be obtained from the dissolved blood-corpuscles was shown by mixing a small quantity of defibrinated rabbit's blood with a larger portion of frog's serum, when in a short time the mixture assumed a lake color from the dissolved corpuscles, while a precipitate of fibrin floated in it.

That the serum of mammals also acts upon the blood-corpuscles of the frog was shown by injecting the serum of the dog, as free as possible from corpuscles, into the veins of the frog. The urine of the frog shortly assumed a bloody color, which remained for several days; and even after the lapse of a week albumen could be detected in the same.

In regard to transfusion among the mammalia, Dr. Landois' conclusions are as follows:

1. The blood-corpuscles of various animals disintegrate and dissolve in the blood of other species.

Under these circumstances, the previous defibrination of the injected or mixed blood is a matter of indifference.

2. The more rapidly the transfused blood-corpuscles become disintegrated in the blood of the recipient, the more quickly do they become dissolved. Thus, the blood-corpuscles of the rabbit, which are easily disintegrated, become quickly dissolved in the blood of the dog. The rapidity of this solution may be tested by the serum of the transfused blood deprived of its corpuscles, or, if the transfused corpuscles are easily distinguished by their size from those of the recipient, the microscope offers an additional means of determining the time of solution.

3. The dissolved elements attain in part the secretions, particularly the urine. A certain quantity of the dissolved material assimilates itself to the body of the recipient. If small quantities of blood are transfused, and if the disintegration of this blood takes place slowly, bloody coloration of the secretions may be absent.

4. Transfusion with heterogeneous kinds of blood may have a favorable effect in the following way: (a) as it supplies nutritive material to the recipient; (b) as it supplies the acidity of the dissolving blood-corpuscles and fluidity to the blood of the recipient; (c) as it, under certain given circumstances, improves the mechanical proportion of the circulation.

As regards the assumption on the part of the transfused corpuscles of their own peculiar physiological functions, it is scarcely worth while to remark. It must be said, however, that experience in regard to the transfusion of the blood of *closely-allied* species is wanting.

5. The duration of the discharge of bloody urine in cases where this has been observed varies within certain limits. Hæmoglobin and albumen have been detected in the urine within one hour and three-quarters after transfusion, and have in some cases remained present for twelve hours or more. In this respect the quantity and also the kind of transfused blood, as well as the functional activity of the circulation in the recipient, have an influence.

6. When an animal is transfused with blood of another kind, its own blood-cells become in part disintegrated.

Such is the case when the blood-cells of the recipient are easily soluble in the current of the received blood. Herein consists the great danger accompanying transfusions by means of rabbit's blood, the corpuscles of which are so easily dissolved.

7. In animals (as the rabbit) whose blood-corpuscles

are easily soluble, transfusion of many kinds of serum (that of the dog, man, pig, sheep, or cat) produces more or less threatening symptoms, according to the quantity injected. Increase in the frequency of respiration, dyspnœa, convulsions, asphyxia, or even death, may result.

8. Animals whose blood-cells resist disintegration, as the dog, endure the injection of other kinds of serum, as that of the sheep, ox, or pig, without any of these symptoms.

9. In rapid transfusion with large quantities of blood, disintegration of the corpuscles either of the transfused blood or that of the recipient takes place very rapidly. Under these circumstances coagulation from the precipitated fibrin may follow, and death be the result.

Experiment also shows that in many instances, instead of entire solution of the corpuscles taking place upon admixture with a different kind of blood, they simply become heaped together in masses.

When this happens, the transmission of such masses into the capillaries of the lung may give rise to the most serious symptoms.

The dangers occurring from transfusion with different kinds of blood vary, as may be seen from what has been above stated, according to the kind of animal.

As has been stated, also, many more experiments are needed in this direction in order to arrive at more certain conclusions.

Dr. Landois hopes in a future paper to give the results of further experiments in this direction, more particularly with a view to the therapeutic uses of transfusion with heterogeneous kinds of blood.

WILLIAM ASHBRIDGE, M.D.

OVARIOTOMY.

DR. FRANZ HOFFMANN reports (*Berliner Klinische Wochenschrift*) two cases of ovariectomy recently performed by him in Wiesbaden. In the first case the patient was a widow, aged 52 years, who had been married sixteen years, had always menstruated regularly, but had never borne a child. The contents of the ovarian cyst had been more than once drawn off by puncture, but finally it was determined to perform ovariectomy. On the 27th of November the patient was placed under the influence of chloroform, and the operation performed. The cyst was emptied of its contents, and, as no adhesions were found, its removal was attended with no difficulty. A double silken ligature was passed through the pedicle and tied upon either side of it. After the pedicle was cut, two arteries of considerable size were seen in the stump; and, to be still more secure against hemorrhage, the actual cautery was applied to the cut surface. Examination showed the left ovary to be sound. The stump of the pedicle was then returned into the abdomen, the abdominal cavity cleansed with spongia, and four deep and nine more superficial silk sutures introduced to unite the wound. On the 17th of December, twenty-one days after the operation, the patient passed with the stool a large piece of gangrenous tissue, upon which, however, no ligature was found. After this, the diarrhœa, from which she had suffered for some time, ceased, and the patient improved rapidly and was able to leave her bed on the 21st of the same month. For a long time there was a painful induration in the region of the sigmoid flexure of the colon, which slowly disappeared; and now, eighteen months after the operation, the patient is in perfect health.

The patient in the second case was a married woman, aged 28 years. She had been married a year, was of good constitution, though somewhat reduced in flesh; and her menstrual functions had always been normally

performed. She first noticed the swelling of her abdomen at Easter, 1872, and in December of the same year tapping was performed, and about twenty-one litres of fluid drawn off. The operation of ovariectomy was performed on the 26th of February, 1873. The operation was performed as in the other case, but, as some adhesions of moderate strength were found, more time and skill were required in extracting the cyst from the abdomen. The scalpel had to be used to separate some of the adhesions; and when these contained vessels the catgut ligature was applied and cut off close to the knot. The pedicle was cut, and in this case secured with a ligature of iron wire drawn through Koeberle's *serre-nœud*. The pedicle was drawn to the lower angle of the wound and secured, and the wound closed. The menses appeared twenty-two days after the operation, and, as has been frequently noticed, a small hemorrhage took place from the granulating end of the pedicle. On the twenty-seventh day the patient left her bed, and was discharged cured on the thirty-ninth day after the operation. At present—three months have elapsed—she is in good health, and stronger than before the operation. Dr. Hoffmann feels much better satisfied with the treatment of the pedicle adopted in the latter case, and thinks that the probability of its becoming encapsulated when ligated and returned into the abdomen is not great, as would be supposed from the results obtained in experiments made on animals. The results obtained from the carbolyzed catgut ligature in the abdomen were very satisfactory.

WILLIAM ASHBRIDGE, M.D.

ELIMINATION OF PHOSPHORIC ACID.

E. MENDEL (*Archiv f. Psych. und Nervenkrankh.*, 1872) has observed—1. That the amount of phosphoric acid excreted during nine hours of night is less than that excreted during the remaining fifteen hours of the twenty-four, but that the hourly amount is usually greater during the night. 2. That in patients affected with lesions of the brain of long standing, as a rule, the amount of phosphoric acid excreted is, both absolutely and relatively to the remaining solids excreted, less than that found in the excretion of healthy persons upon the same diet. 3. That in cases of maniacal excitement the phosphoric acid in the secretions is diminished both relatively and absolutely, while it is increased after apoplectic and epileptic seizures. He also noticed that after sleep had been induced by the use of hydrate of chloral or potassii bromidum a marked increase in the amount of phosphoric acid excreted took place.

WILLIAM ASHBRIDGE, M.D.

BACTERIA IN THE BLOOD.—It is now pretty generally agreed that Bacteria are almost invariably present in the blood: therefore the following record is not so surprising as it might have been a few years ago. It seems that Dr. Eberth states (in *Centralblatt*, No. 20, 1873) that he has found in ordinary sweat, as well as in yellow sweat, small oval-shaped Bacteria, which are frequently united in strings of two or three, and endowed with rather active movements. In spots covered with hair they attach to it and often form thick layers; whilst others penetrate into the hair, which then splits and breaks. Coloring by means of hæmatoxylin brings out the isolated Bacteria, as well as those collected on the hair. The author thinks that they very likely contribute to produce certain chemical modifications of sweat.—*London Monthly Microscopical Journal*, January, 1874.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, FEBRUARY 28, 1874.

EDITORIAL.

CHANG AND ENG.

IN *Lippincott's Magazine* for March is an account of a visit to the original home and to the parents of the Siamese Twins. The latter, it appears, were born some thirty miles southwest of Bangkok; their father being a Chinaman, their mother a native of Siam, bred by a Chinese father. The twins were, therefore, three-fourths Chinese, and were known in their native home as the "Chinese Twins." They were the first-born sons of their parents; but their mother has presented her husband with four other pairs of twins and four children born at single births,—all of them normal and healthy. Their mother, during their infancy, entirely recognized their separate individuality, and also the fact that there existed a common sensibility in the centre of the band. She stated, what is undoubtedly true, that at first the ligament was so short that the boys were compelled always to be face to face; even in the bed they could not turn without being lifted up and placed in the desired position. As they grew, the ligament seemed gradually to stretch, until they were able to stand side by side, and even back to back, and to turn themselves in bed by rolling one over the other. The father being a fisherman of the laboring class, the boys lived in one of the floating houses of the country, and soon became famous swimmers, spending much of their time in the river. It was the peculiarity of their movements in the water which first

attracted the attention of a Scotch merchant, Mr. Robert Hunter, and finally led to their leaving their native country in quest of fortune.

Altogether, the history of their life is a very strange one,—commencing in a Siamese sampan, ending in the backwoods of North America,—a life beginning in the utter obscurity of a fisherman's hut, passing out amidst such noise and notoriety as falls to the lot of only one mortal in ten millions.

OWING to the unavoidable haste in preparing the number of this journal which was devoted to a consideration of the Siamese Twins, there occurred the following errata:

Dr. Pancoast was incorrectly reported as using the expression *Omphelopagus Xiphodidymus*, as applying to the monstrosity under consideration. The term which he employed was *Omphaloxiphodidymus*.

On p. 324, Dr. Allen should have been quoted as saying, "On the posterior side there was a fold underneath the skin extending from a *central point in the abdomen* of Chang," and not "from the ensiform cartilage."

WE have long suspected that the French "con-cours" system is in practice not so perfect as some of its supporters claim. It is very conceivable that a most distinguished originator of new ideas, and a most learned man, might not be so ready as a really less able but an intellectually more agile opponent, and might not under pressure shine so much as the lesser light. The fuel that blazes quickest and fiercest does not always contain the most heat-power. Speaking of the opening address of the newly-chosen professor of the history of medicine at Paris,—M. Lorain,—the correspondent of the London *Lancet* says,—

"The influence of physiology was forcibly shown, and in connection therewith the lecturer expressed his regret that the School of Medicine and the Paris hospitals had not secured a man like Claude Bernard, who, like many others, had found it impossible to submit to the 'corset' of public competition."

WE desire to call the attention of the Fellows of the College of Physicians to the fact that the Journal Association is very much in need of funds. In the absence of Dr. Bache, subscriptions may be paid at the college or to the authorized

agent, who will call upon the Fellows. The continuous success of the enterprise is a *necessity* for the growth of the college. There are, at present, thirty-six periodicals subscribed for by the association, of which twenty-seven are European. These are in addition to those taken by Dr. Lewis and by the college, so that the whole makes a very complete list. The objects of the association are briefly explained in their annual circular, as follows:

"Objects.—1. To obtain for the use of the Fellows medical journals *promptly*, as the numbers are issued.

"2. To increase the College library.

"The journals are placed on the table in the library as soon as received, and there remain, accessible to the Fellows, until a volume is completed, when it is turned over to the library and becomes the property of the College. In 1873 thirty volumes were thus given to the library."

OUR LEARNED COTEMPORARIES.

WE see from our homœopathic exchanges that Dr. Hering has discovered that the conjunctions and disjunctions of the moon and the sun are potent in their influences upon the actions of remedies, and Dr. Morgan has found that Jupiter is but little less powerful. Evidently a slice of the Middle Ages has been projected into our midst, and once more astrologers and physicians will be like the two single gentlemen of the poem,—rolled into one. Dr. Hering will be happy to furnish monthly tables to any who may desire astrological guidance.

PROF. A. L. CLINKSCALES asks in *The Archives of American Medicine and Surgery* (eclectic), "Where and what are we?" We don't wonder at an eclectic editor asking this: we think only inspiration could answer it.

"Home went the little woman, all in the dark;
Up got the little dog, and he began to bark;
He began to bark, so she began to cry,
'Lawd a mercy on me, this is none of I!'"

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

DR. W. B. ATKINSON, PRESIDENT, in the chair.

A CONVERSATIONAL meeting was held December 10, 1873, at 8 o'clock P.M.

The presentation of books, specimens, etc., being in order, Dr. BENJAMIN LEE presented to the library of the society a volume entitled "The Mechanical Treatment of Disease of the Hip-Joint," by Dr. Charles Fayette Taylor, Surgeon to the New York Orthopædic Dispen-

sary and Hospital, etc., etc. The work, Dr. Lee said, was, as its preface stated, strictly confined to the subject indicated by its title,—the mechanical problem involved in the distortions resulting from inflammation of the hip-joint, and the mechanical appliances necessary to relieve them. It did not pretend to enter into the broad field of pathology or of general treatment. It contained, of course, a careful description in detail of the author's apparatus or splint for producing extension without interfering with locomotion, which, like all hip-splints, was a modification of the original Davis's splint; its principal features being that its lower extremity rested on the ground, and was quite independent of the shoe. The chief merit of the book, however, Dr. Lee thought, was to be found in the fact that its author proposed to divide the process of overcoming the muscular contractions which form so serious a complication in the disease, into two distinct stages, founded upon the order in which these contractions take place. In so doing he was carrying out, perhaps unconsciously, the idea so happily suggested by William Adams, of London, in regard to the treatment of the contractions in talipes varus. This gentleman proposed to reduce the compound distortion to the simple form of equinus, by first overcoming the lateral distortion through the transverse tarsal articulation, and then dealing with the contracted gastrocnemius and the deformity of the ankle-joint proper.

Dr. Taylor's proposal in regard to the compound contractions existing at the upper part of the thigh, which he had already for some time put into successful practice, was to overcome, first, the contraction of the adductors, inasmuch as they are the last to become shortened; and, after we had entirely succeeded in accomplishing this object, to direct our attention to stretching the contracted flexors, but not until then. His mode of procedure was described by Dr. Lee as follows, the demonstration being illustrated by means of a portion of a splint which he had already had in use, and which differed from Dr. Taylor's in but slight modifications. Any one seeing for the first time a patient with disease of the hip-joint, lying on the back, with the limbs side by side upon the bed, both equally flat, would conclude upon a cursory examination that there could not be any contraction at the hip. If, however, he should pass his hand under the back, in the lumbar region he would at once perceive that the spine was arched up to a much greater extent than is natural, and that only by drawing up the affected limb to a considerable angle with its fellow could the spine be brought down to its proper position. Dr. Taylor, before applying his splint, places the limb upon an inclined plane adjusted carefully at exactly this angle, so that there shall be no spinal distortion. The sound limb being in the line of the axis of the body, the affected limb lying upon its inclined plane probably crosses it below the knee. The splint is then put on, and slight extension made. At the same time a powerful screw, acting upon the hip-band of the splint, throws its lower end out from the median line, thus acting against the contracted adductors, as the hip-band is held firm by a perineal strap upon the opposite side. To complete this process of relaxation occupies from a few hours to ten days; and until it is fully completed, the efforts must not be intermitted or relaxed. Having accomplished it, however, the inclined plane is slowly lowered, and the flexors, being now alone in maintaining the deformity, yield with its descent, until the limb is on the plane of its fellow and the pelvis at its natural inclination to the femur. The patient is then allowed to assume the erect posture and to attempt locomotion. By thus methodizing the extension, the author claims that a resort to tenotomy will very rarely be necessary. This idea Dr. Lee considered to be entirely new so far as the

hip-joint was concerned, and to give the book sufficient value to entitle it to a place upon our shelves.

Dr. P. D. KEYSER presented a specimen sent him by Dr. SCHITTLER, of Jefferson, Wisconsin, of the larva of the *Eristalis tenax* (the rat-tail fly), which was removed alive from the nostril. Dr. Schittler sent it October 4, 1873, and wrote that about six or seven months previously Mrs. Marsue, of Jefferson, came to him complaining that something was the matter with her nostrils; she was sure that something living was inside of them, as she could feel it moving about slowly from place to place. By careful examination with reflected light and a speculum, nothing but a hypertrophied condition of the mucous membrane lining the canal could be seen. He ordered her a nasal douche of carbolic acid solution, but without any permanent effect. After four weeks' treatment she left him, but continued using different innocent washes, until October 1, when she returned again, begging him to make a more thorough examination, as she could very distinctly feel the worm creeping about, at times going back towards the Eustachian tube, and then forward again. He again examined her, without discovering anything but the former condition, and again ordered injections of carbolic acid solution. On the 4th of October she again returned, and besought him to examine, as she felt the thing was quite in the front of the canal. On examination, to his surprise, he saw and drew out with forceps a worm about half an inch long, with a tail of the same length. He put it in water, and it swam about actively, with the tail erect. The same evening, at 10 P.M., he put it in a small vial containing alcohol and glycerin, and sent it by mail to Dr. Keyser for examination. After making a microscopical drawing of it, Dr. Keyser took it to Professor Joseph Leidy, who pronounced it to be the larva of the *Eristalis tenax*. It must have been snuffed up the nose from using water in which these larvæ were, and has continued to live in this state without transformation this length of time. There are certain peculiar conditions which prevent the transformation of larvæ into the insect, and this may have been the case in this instance, as this insect has never been known to be a parasite to man.

Dr. O'HARA stated that he had recently treated a compound fracture of the thigh in which there was shortening of one inch. He desired to ask the surgeons present what would be called a common and good cure.

Dr. D. HAYES AGNEW replied that fractures of the thigh were rarely cured without appreciable shortening. If the shortening did not exceed half an inch, or even three-fourths of an inch, the cure was not a bad one. Such fractures are rarely transverse, but oblique, at least in civil practice. In children better results as to length are obtained, but not what may be termed perfect.

Dr. W. L. ATLEE could see no reason why the limb, three hours after the fracture, could not be reduced to its original length by extension and counter-extension, under the influence of an anæsthetic. Had sufficient time elapsed after the accident for inflammation to be established in the injured parts before an attempt at extension was made, he could understand the difficulty. His remarks applied only to the first efforts at extension, and not to the result of subsequent treatment, which rarely accomplishes a perfect cure.

Dr. STETLER thought an impacted fracture might account for the difficulty in Dr. O'Hara's case.

Dr. LEE asked Dr. O'Hara whether he concluded that there was shortening of the femur because the heel of the affected side could not be brought down to the same point as that of the sound side, or from actual demonstration of overlapping of the fragments at the seat of injury, or from measurement of the femur from trochanter to external condyle. If the first indication

were relied upon solely, might not the shortening be due to dislocation upwards of the head of the femur, which the gravity and urgency of the principal lesion had caused to be overlooked?

Dr. O'HARA said there was no dislocation.

Dr. G. KERR then read a paper on the "Use of Alcohol Medicinally and Socially."

Dr. B. LEE said that he felt that it did us, as members of the medical profession, no harm to have the subject which had been discussed this evening brought to our attention from time to time, and that when one of our own number offered us a word of exhortation and of caution in this regard it behooved us to receive it with a good grace, and to give the matter thoughtful consideration. Alcohol is certainly a two-edged sword. When it fails to cure it may kill, and we cannot hedge in our exhibition of it with too many precautions. He must say, however, that the paper presented this evening was, to his apprehension, more of the nature of a temperance lecture than of a scientific essay. The subject had not been treated in that spirit of fair, searching, discriminative investigation which would enable us to discuss it intelligently. The author had referred in the course of it to the writings of two distinguished English physicians and physiologists,—Carpenter and Anstie. The former of these has been for years the bright and shining light of that school who desire to show that alcohol can never be of any possible use to the human body, the result of his experiments being, in his own view and that of his followers, that all the alcohol taken into the body is rejected by it in the various excretory processes, and that it is therefore evidently regarded by the tissues as simply an intruder, and a poison. These experiments have, however, been completely overturned by later investigators, and by none more completely than by Anstie, whom the lecturer has quoted approvingly on one side of the question, while his views on the opposite side have been passed over in silence. His recent experiments led him to the conclusion that a healthy adult man can appropriate two ounces of alcohol in the course of twenty-four hours, no trace of which or of its constituents can be found in his excreta. We must conclude, then, that it has undergone a conversion into tissue, and therefore is to be regarded in the light of a food.

Dr. J. G. STETLER asked Dr. Kerr what substitute besides "Schuylkill water flavored with Knickerbocker ice" he proposed giving the American Medical Association in the place of alcohol.

Dr. F. J. BUCK thought there ought to be a law which would allow friends to confine habitual drinkers as insane, on certificate.

REVIEWS AND BOOK NOTICES.

A HANDBOOK OF THE THEORY AND PRACTICE OF MEDICINE. By FREDERICK T. ROBERTS, M.D., B.Sc., M.R.C.P. Philadelphia, Lindsay & Blakiston, 1874.

Dr. Roberts has succeeded admirably in the performance of a very difficult task,—the condensation into a moderate-sized volume of the main facts connected with the pathology, symptomatology, and treatment of disease,—and in doing so he has produced one of the most satisfactory medical handbooks in the language. He states modestly in his preface that the work is intended mainly for the use of students, and that its object is to present in one volume such information on the principles and practice of medicine as shall be sufficient to prepare them for their various examinations, and also to guide them in acquiring that clinical knowl-

edge which alone can properly fit them for assuming the active duties of their profession. Judged by this standard, it is not just to complain that the book is not so lucid and comprehensive as Flint, so entertaining as Watson, or so scientific and copious in its pathology as Aitken, but we should simply inquire whether its object has been accomplished, and whether it supplies a recognized deficiency in medical literature. In the first place, the general arrangement of the work is excellent, both for convenience and ready reference, and for the systematic study of disease. Before entering upon the consideration of the affections of any special organ or sets of organs, a general outline is given of the clinical phenomena which indicate a morbid condition of those parts, with a summary of the symptoms and physical signs presented by each under varying circumstances. The remarks on diagnosis, prognosis, and treatment are clearly and concisely generalized.

The first section, on the etiology and semeiology of disease, while it might perhaps have been omitted without lessening the value of the work to the general practitioner, yet contains many valuable hints to students on matters which they are too apt to overlook.

In the second section are considered certain morbid conditions of which it seems desirable to have a comprehensive knowledge before studying them in connection with special diseases. These include congestion, dropsy, hemorrhage, inflammation, pyrexia, etc.; and, without entering into any minute histological disquisitions, the subjects have been fairly brought up to the level of the present day.

The third section is devoted to the consideration of individual diseases and their clinical investigation. The faults throughout this portion of the book are, as in every compend, chiefly those of omission.

Under scarlatina there is no mention made of atrophy of the optic disks as a sequel to that disease, although it is not infrequent and is of great importance. In the article on gout very little is said about the employment of mineral waters, and no distinction is drawn between their different varieties. In the very brief mention which is made of gonorrhœal rheumatism, there is no allusion to the idea that the disease may be of pyæmic origin. In discussing the treatment for tænia, the author does not allude to the use of pumpkin-seed, although that was long ago proven to be a valuable and reliable remedy in such cases. Under dysentery, there is no mention made of injections of ice-water or of chlorate of potassium; both, it seems to us, deserving of a passing notice.

In the article on sunstroke, there is evidence of a want of familiarity with American authorities on that subject.

These are, of course, but trifling and excusable errors, and, although their enumeration might be prolonged, the foregoing will serve as sufficient examples.

The introductory remarks to the diseases of the circulatory organs are particularly lucid, and will doubtless help many to a clearer understanding of the somewhat complicated subject and of the physical symptoms apparent in these affections.

The diseases of the lungs and pleuræ are excellently discussed, and perhaps constitute the most praiseworthy portion of a work which is very creditable to its author, and which is likely to be of great service both to students and to practitioners.

LECTURES ON THE CLINICAL USES OF ELECTRICITY. By J. RUSSELL REYNOLDS, M.D., F.R.S. Second Edition. Philadelphia, Lindsay & Blakiston.

We are glad to see a second edition of this little manual, which, to our thinking, for students and for general practitioners is simply the best book in the language upon the subject of which it treats. Clear, concise, containing pretty much all that is worth know-

ing, it is singularly free from the farrago of fallacies and nonsense which encumber so many treatises upon electricity. We greatly fear that the edition is a pirated one, and only wish medical public opinion was strong enough, in the absence of a copyright law, to make self-interest and justice synonyms in the American publishers' dictionary.

AN INTRODUCTION TO PHYSICAL MEASUREMENTS, WITH APPENDICES ON ABSOLUTE ELECTRICAL MEASUREMENTS, ETC. By DR. F. KOHLRAUSCH. Translated from the Second German Edition by THOMAS HUTCHINSON WALLER, B.A., B.Sc., and HENRY RICHARDSON PROCTOR, F.C.S. New York, D. Appleton & Co., 1874.

A very learned book, a very abstruse book, which we fear will not be appreciated by the medical profession. Indeed, the only part of any possible interest to physicians is that which treats of the absolute measurement of electric force. A glance over its abstruse formulæ has convinced us that a modification of Laplace's saying to Mrs. Somerville may be applied to the physician who reads them: "You and Miss Fairfax are the only woman who has read my *Mécanique Céleste*."

THE MICROSCOPIC STRUCTURES AND MODE OF FORMATION OF URINARY CALCULI. By H. VANDYKE CARTER, M.D. Lond., with Illustrations. 8vo, pp. 51. London, J. & A. Churchill, 1873.

This brochure is a praiseworthy effort in a field not explored, systematically at least, previous to the labors of Dr. Carter. Much valuable information, liberally illustrated, is added to our knowledge of the physical and chemical composition of calculi.

Dr. Carter believes that the microscopic analysis of urinary calculi is "not only more valuable, but that it is even more delicate, than the chemical method," and by its aid is still more clearly shown than before that "no single urinary deposit long occurs alone." That this fact is beautifully confirmed by microscopic examination is true; but microscopic analysis cannot be said to be more certain than chemical analysis, the well-determined facts of which are beyond dispute, and the fact of the mixed composition of urinary calculi has long been one of these. To be able to *confirm* chemical results is, however, sufficiently good work for microscopical inquiry; and in this respect Dr. Carter has done very valuable work.

We had hoped to find, as the result of Dr. Carter's researches, some more certain indications than we now possess of the exact nature of existing calculi, from a study of the microscopical and chemical characters of the urine; but we regret to find nothing more definite than heretofore. The difficulty in the dispersion of calculi by chemical means is explained by the large amount of animal matter always present, which, when the salts are removed by solution, remains behind in the shape of a stubbornly insoluble membranous matrix.

LECTURES ON BRIGHT'S DISEASE, WITH ESPECIAL REFERENCE TO PATHOLOGY, DIAGNOSIS, AND TREATMENT. By GEORGE JOHNSON, M.D., F.R.S., Fellow of the Royal College of Physicians, Professor of Medicine to King's College Hospital, etc. 12mo, pp. 152. New York, G. P. Putnam's Sons, 1874.

Anything from the pen of Dr. Johnson on the subject of Bright's disease is welcome. A pioneer in the true pathology of the subject, it is pleasant and useful to read his views as confirmed or enlarged by the result of many years' experience and study. The present volume, dedicated to his past and present pupils, is a reprint of some lectures published during the past year in the *British Medical Journal*, and may be said to represent his present views. These have not materially altered from those presented many years ago in his

larger volume, but are presented in a form easily available to the busy practitioner. When we say that in both pathology and treatment he more nearly approaches than any other author what we conceive to be the correct notion, and that the practitioner and the student will find all that is essential to guide him to the most successful treatment possible of Bright's disease, we feel that we have said all that is required.

GLEANINGS FROM OUR EXCHANGES.

THE VALUE OF TENOTOMY OF THE TENSOR TYMPANI MUSCLE.—At the annual meeting of the American Otological Society in 1873, Dr. R. M. Bertolet read an interesting and instructive paper upon the above subject. He believes that the operation is bound to become one of the most important remedial measures at the disposal of the aural surgeon, when the comparative simplicity and harmlessness of the procedure are more generally recognized, the indications more clearly enunciated, and when it is not resorted to merely as a *dernier* measure. The precise process leading to rigidity and shortening of the tensor tympani muscle is not yet determined. The patient's history is generally one of progressive difficulty of hearing, with tinnitus aurium, fulness in the ears, vertigo, etc. The membrana tympani is seen to be unusually concave; frequently the promontory is seen shining through the membrane, and the handle of the malleus is drawn inwards so as to appear foreshortened.

Dr. Bertolet gave the following table of sixteen cases in which the operation had been performed:

No.	Sex.	Age.	Ear operated upon.	Duration of the affection in years.	Hearing, distance for which before the operation.	Hearing-distance after division of the tendon.	Remarks.
1	F.	45	L.	7	Contact.	Only temporary cessation of the tinnitus.
2	M.	50	L.	8	o	Contact.	Cessation of the noises.
3	M.	50	R.	8	6"	Cessation of the noises.
4	M.	41	L.	5	o	Otitis media purulenta set up.
5	M.	39	R.	2	o	12"	Complete cessation of the noises.
6	F.	28	L.	years?	Contact.	Resulted in a purulent inflammation of the middle ear.
7	F.	28	R.	years?	o
8	M.	60	L.	3	Contact.	Contact.	Diminution of the tinnitus.
9	F.	19	R.	2	2"	36"	Entire subsidence of the tinnitus in both ears.
10	F.	19	L.	2	3"	36"
11	F.	47	L.	4	o	Contact.	Diminution of noises, eventually worse.
12	M.	36	L.	3	Contact.	Contact.	Noises disappeared in both ears.
13	M.	36	R.	3	1"	1"
14	M.	62	L.	12	o	o	Noises greatly diminished.
15	M.	62	R.	12	o	o	No improvement.
16	F.	47	R.	4	1"	1"	Noises only slightly relieved.

CASE OF ACARDIA (*New York Medical Journal*, February, 1874).—Dr. Lusk reports a case of twin pregnancy,—labor occurring in the seventh month,—in which the birth of the first child was followed thirteen hours later by the delivery of an acardiac monstrosity, weighing three pounds and nine ounces. The lower extremities as far as the feet were well developed. A loop of intestine protruded from the umbilicus. The upper portion of the foetus consisted of two globular

sacs, composed of skin, which was greatly hypertrophied, and through which a distinct fluctuation could be made out. There was a small bunch of hair at the upper junction of the sacs. The cervical, dorsal, and lumbar vertebrae were complete, but the sternum was absent. There were no traces to be found of either heart, lungs, stomach, pancreas, liver, or spleen.

The accepted theory of the origin of this monstrosity is as follows. The acardia is always one of twins. Both children are developed from the same ovum, are of the same sex, and are contained in a single chorion. There is a single placenta, but two capillary systems, which communicate. Sometimes, by means of large connecting vessels, the two foetal circulations in the placenta form a more intimate union with each other. Then, in case each foetal heart beats with equal intensity, the result would be an arrest of the circulation in the communicating branches, with the formation of thrombus. When the heart's action in one foetus counterbalances that in the other, the stronger blood-current in the placenta would push back the weaker one, at first impeding the circulation of the latter, then arresting it, and finally causing it to take an inverse direction. The heart then atrophies, and, the force not being sufficient to carry the blood-current to the upper parts of the body, they are consequently not developed.

FRACTURE OF THE SKULL, WITH CHRONIC ABSCESS (*Edinburgh Medical Journal*, December, 1873).—Dr. James More reports the case of a young man who was injured by the bursting of a gun. When seen, he was sitting quietly by his fireside, apparently not much the worse for the accident. There was a stellate wound right in the middle of the frontal bone, about the size of a garden pea; there was no pain, and little or no hemorrhage. On the introduction of a probe, fracture of the bone was found, and the probe went easily and straightly into the substance of the brain. He was ordered perfect quiet, a mild aperient, and milk diet. At the end of a week he felt and seemed quite well, and remained so for two months. In about ten weeks, however, he began to complain of headache, slight sickness, and giddiness; his temperature became irregular, and he had exophthalmos, with enormously dilated pupils. He became profoundly comatose, and died just thirteen weeks after receipt of the injury. At the post-mortem examination a small canal was found leading antero-posteriorly from the frontal wound into an abscess. The latter was the size of an orange, and was situated just above the right ventricle, the roof of which formed the floor of the abscess. The meninges in the neighborhood were thickened, but otherwise the brain and all its coverings were healthy.

A TEST FOR CARBOLIC ACID (*Journal of Applied Chemistry*, February, 1874).—Plugge has observed that when a solution containing carbolic acid is mixed with a solution of the subnitrate of mercury, not only is the mercury reduced, but the liquid acquires an intense red color. Further experiments showed that the presence of traces of nitrous acid was essential to this reaction, and that it could be employed as a test for carbolic acid. He found that the color was still quite evident when only one sixty-thousandth part of carbolic acid was present. Still smaller quantities could be detected by this test if carefully applied, but the amount of nitrous acid must be very small.

PRECOCIOUS MENSTRUATION (*American Medical Journal*, February, 1874).—Dr. A. F. Deniston reports the case of a female child in whom the menses first made their appearance at the age of twelve weeks and have since recurred with unfailing regularity. The girl is now eleven years of age; her breasts are fully developed, and she appears much older than is natural.

MISCELLANY.

THE WOMAN QUESTION VIEWED CHEMICALLY.—“She is large, ruddy, and plump, a good-looking, strawberry-and-cream woman, but one of these negative ones,—a perfect *Pulsatilla* case,” said Mrs. Dr. —. The above suggested the following train of thought: “Fleshy and negative,” then lean and positive, must be the other extreme. There is an idea for you. But is it a fact? If so, let us see where it leads us. Woman is more fleshy than man. Woman is negative; man, as a rule, is positive. Women are not as fleshy as they were formerly, therefore they are more positive. American women are the leanest of the lean, therefore American women are the most positive, *i.e.*, the most strong-minded and aggressive, or, in other words, more masculine-like, and less womanly, and of necessity less motherly. If that is so, then the Turk who fattens his women with bread and honey is a sage and a physiological philosopher. His women are fat and contented, and peace reigns in his harem. Then the triumph of the woman question turns upon a little more acid. Fat is negative and alkaline; lean is positive and acid. Sweets, starch, and fats are fattening, while acids, stimulants, and spices take off fat. Quiet and water increase the fat, while activity takes it off. Now, there is a hint for the women who would be “man’s equal,” *i.e.*, equally positive. Agitate, stir up the sisters, condemn bonbons, insist on a little more pickles and all the spices you can get, and do not object to tobacco (smoke) and (bay) rum. What a ray of hope for hen-pecked husbands! How they can quietly and effectually flank and subdue the turbulent element with sweets, soups, fish, and a little more mutton. There is, however, a large, intelligent, and growing brain that cannot thus be subdued, and, thank the Lord, these are “too wise to err and too good to be unkind.”—*The Medical Investigator (Homœopathic)*.

IS SULPHATE OF MORPHIA INCOMPATIBLE WITH COMPOUND SPIRIT OF ETHER?—A writer in the *Druggist’s Circular* says, “A short time ago I prepared the following prescription:

R Sulphate of morphia, 3 grains;

Compound spirit of ether, 2 ounces.

Mix. Dose, a teaspoonful at night.

“About two weeks afterwards the bottle was returned; there was about a quarter of an ounce of liquid left in the vial, and I noticed it was full of small crystals of morphia. I made a solution of sulphate of morphia in alcohol, and kept it two days without any change intervening, when, a small quantity of ether being added, the whole of the sulphate of morphia crystallized out in the space of twenty-four hours. Had the patient taken the last dose, with all the crystals in it, the result would have been quite serious.”

EASTERN HONORS TO AN AMERICAN SURGEON.—According to the *Lynchburg Republican*, Dr. Edward Warren is extremely successful in Cairo. It says he

is at present chief surgeon to the staff, ranking as colonel, with a salary of \$300 a month, and the privilege of practising his profession. The doctor had treated the Minister of War for a disease after he had been given up to die by the physicians of Cairo, and the patient recovered, which was looked upon as almost a miracle. He was officially thanked for saving the minister’s life. The viceroy issued an order making the doctor a Bey, and giving him a decoration, and he has since been overrun with practice.

NOTES AND QUERIES.

KENTON, OHIO, February 28, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

Can you inform me in what manner croton chloral is used—whether dissolved or in powder, or in what does it dissolve—and also its dose? An answer to this would be a favor.

Very truly yours,
C. H. SMITH.

Answer.

Croton chloral is to be given in doses of from ten to twenty grains, dissolved in syrup; in poisonous properties it is *probably* about equal to chloral.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

In the number of the *Richmond and Louisville Medical Journal* for October, 1873, a writer speaking of lithotomy says, “The records show a greater percentage of success in it by a Kentucky surgeon, even to this day, notwithstanding all the modern improvements. I speak of Dr. Benjamin F. Dudley, of Lexington.” I have heard the same thing claimed for Prof. Paul F. Eve, of Nashville, Tenn. Which of these claims is correct? Am I wrong in thinking Prof. Gross has attained at least as high a percentage of success as either of these gentlemen? By giving me the required information, and the statistics of the operation, through the columns of the *Medical Times*, you will greatly oblige

A YOUNG SURGEON.

Answer.

We would be obliged for an answer from some surgical subscriber.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM FEBRUARY 10, 1874, TO FEBRUARY 23, 1874, INCLUSIVE.

EDWARDS, L. A., SURGEON.—Leave of absence extended fifteen days. S. O. 29, Military Division of the Atlantic, February 16, 1874.

GHISELIN, JAMES T., SURGEON.—Relieved from duty as Attending-Surgeon at Portland, Oregon, to enable him to avail himself of his leave of absence. S. O. 18, Department of the Columbia, February 4, 1874.

RANDOLPH, JOHN F., SURGEON.—Assigned to duty as Chief-Surgeon with troops under orders for field-service in the vicinity of Fort Laramie, Wyoming Territory. S. O. 22, Department of the Platte, February 14, 1874.

HEITZMANN, C. L., ASSISTANT-SURGEON.—Assigned to duty with troops under orders for field-service in the vicinity of Fort Laramie, Wyoming Territory. S. O. 22, c. s., Department of the Platte.

ROSE, GEORGE S., ASSISTANT-SURGEON.—Assigned to temporary duty at Yuma Depot. S. O. 11, Military Division of the Pacific, February 9, 1874.

CLEARY, P. J. A., ASSISTANT-SURGEON.—To report in person to the Commanding-General, Department of the Missouri, for assignment to duty. S. O. 34, A. G. O., February 16, 1874.

WIGGIN, A. W., ASSISTANT-SURGEON.—Detailed temporarily for duty as Attending-Surgeon at Portland, Oregon. S. O. 18, c. s., Department of the Columbia.

SATURDAY, MARCH 7, 1874.

ORIGINAL COMMUNICATIONS.

CASE OF SMALL ROUND-CELLED SARCOMA.

BY CHARLES B. NANCREDE, M.D.,

Assistant-Surgeon P. E. Hospital.

THE patient, Lizzie H., æt. 13 years, first complained of pain in the right side of the thorax, which ceased within forty-eight hours, and then recurred only after the lapse of two or three weeks. On examination by her mother, a small tumor, the size of a hazel-nut, was found about the middle of the outer surface of one of the lower ribs, probably the seventh. I first saw the patient on November 14, 1872, at the University of Pennsylvania, where I was then acting as Dr. Strawbridge's chief of clinic. She then had diplopia, owing to paralysis of the external rectus of the right eye, and also suffered from pains over the right brow and side of the head. The diagnosis then made was that of intracranial tumor, compressing the right abducent nerve. At a subsequent visit, she complained of "the lump in her side,"—now increased to the size of a hen's egg,—which was diagnosed by Prof. Agnew, Dr. W. F. Norris, and others, as probably being an enchondroma of the ribs, accompanied by a secondary deposit at the base of the brain, causing the divergent squint. Prof. Agnew declined to remove the tumor of the ribs until the head-symptoms were relieved.

For a month no change in the fundus of either eye could be detected with the ophthalmoscope; later, there seemed to be a slight haziness, and some projection of the right papilla. This, owing to a marked astigmatism, was difficult to determine positively. The patient had frequent attacks of headache, lost strength and flesh, and had a capricious appetite; all the while the tumor was increasing and rapidly involving the adjacent ribs. About January 1, 1873, œdema of the left eyelid was noticed, varying in degree from day to day. In two weeks' time this partially subsided, and a small tumor at the outer part of the orbit, just beneath the superciliary ridge, was discovered. The latter rapidly increased, displacing the eye downwards and outwards, and was occasionally accompanied by marked œdema of the lids. After each attack of œdema there was a decided increase of the tumor. The vision of the eye was not affected.

During the latter part of June, 1873, the same condition supervened in the right orbit: both of the growths enlarging, bulging upwards and outwards the orbital plates of the frontal bone, with protrusion of the eyes, injection of the conjunctiva, and, finally, ulceration of both corneæ. There also commenced at this time a small, soft growth on the vertex. During the latter part of July, 1873, another growth commenced on the right masseter muscle. This increased very rapidly, and extended into the back part of the mouth, where ulceration

soon commenced. It became so large, and so involved the muscle, as to cause almost complete closure of the mouth.

During the last three months of life, mydriasis came on in both eyes, commencing in the left, with concomitant loss of sight. From an early period of her illness, she was annoyed by indefinite abdominal pains, preventing sleep, and towards the close of life these became so severe as to require large doses of morphia. At first the general health was good, but latterly deteriorated rapidly. Six weeks before death the patient became totally blind, owing to the destruction of the corneæ from ulceration, and there were repeated hemorrhages from the stumps. For three or four weeks before death there was a slight cough present, and the tumor in the side ulcerated in two places, from which several severe hemorrhages occurred. At this time she also suffered from deafness of the right ear. She died quite suddenly, during sleep, on November 1, 1873.

In the post-mortem of the above case I was assisted by Dr. F. P. Henry, who kindly made for me the following notes:

A large hemispherical tumor occupied the left anterior half of the frontal bone, and extended below it, so as to involve the orbit and its contents. Its transverse diameter extended from the root of the nose to a little beyond the external angular process of the frontal bone; its perpendicular diameter, from the infra-orbital ridge nearly to the commencement of the hair. The eyebrow crossed the tumor at its centre. A similar tumor occupied the right side of the frontal bone, but was situated more externally, its centre corresponding to the external angular process, with a radius of about an inch. A third smaller tumor was situated over the right masseter muscle, and, by its growth inwards, had involved the alveolar processes of the superior maxillary bone and caused the loss of one of the molar teeth.

Both eyeballs were extruded, but the exophthalmos was more marked on the left side. The balls were completely disorganized, a bluish, semi-transparent disk marking the situation of the cornea; but there was nothing resembling a staphyloma.

On removing the scalp, a number of hemispherical tumors were found beneath the pericranium, varying from the size of a split pea to that of a section of a walnut. These tumors when cut into were yellow-white in color, and of a cheesy consistence. The largest of them was over the posterior fontanelle. There were two on the coronal suture, one in the median line, the other on the right side near the anterior border of the temporal muscle. There was a fourth beneath the left temporal muscle nearly as large as the one over the posterior fontanelle, and a fifth, smaller, at the posterior border of the same muscle. Besides these, there were a number of smaller growths scattered over the cranial surface, from the size of a split pea to that of a section of a filbert. On removing the skull, the largest of these—viz., the one over the posterior fontanelle, those on the coronal suture, and the one beneath the left temporal muscle—were found to be attached

to the dura mater, and involved the bone in its entire thickness. The veins covering the convolutions were engorged with blood,—the venous engorgement being more marked over the right hemisphere. The dura mater, beneath the tumors described, was adherent to the brain. With the exception of these adhesions, the brain was healthy. A small amount of fluid, estimated at one drachm, was found in each lateral ventricle. The tumor observed externally on the left anterior half of the frontal bone was found to be adherent to the dura mater at the sphenoidal fissure and its neighborhood, its point of attachment having a diameter of about an inch. The roof of the left orbit was broken open, and its cavity examined. No trace of eyeball, muscles, or nerves was found, the orbital cavity being completely filled by the tumor.

At the right side of the thorax was a large pyriform tumor, its base extending from the inferior angle of the scapula to the lower border of the ribs, its apex looking outward and projecting from the thorax. It bore a striking resemblance to a mammary gland. At its apex was a circular ulcer nearly an inch in diameter, covered with a grayish-yellow slough; above this was another about half the size, and presenting the same sloughy surface. This tumor was but a portion of a much larger growth, which occupied about three-fourths of the right pleural cavity, displacing the lung upward and backward, and compressing it to such an extent that its tissue was not readily recognized. The left lung was healthy. Both ventricles of the heart were filled with fluid blood. The liver occupied a lower position than normal, being apparently crowded down by the tumor in the thorax.

On microscopic examination were found the ordinary cell-elements of small round-celled sarcoma,—viz., round, and, in some portions, spindle-shaped, nucleolo-nucleolated cells, imbedded in a delicate, faintly-fibrillated stroma.

There are several points of interest connected with this case, to which I shall briefly refer. According to Knapp, changes in the ophthalmoscopic appearances of the eye generally accompany intra-orbital growths, and necessarily do so when the optic nerve is involved. But in this case there was no appreciable change in the fundus of either eye, even within a few months of death, although there must necessarily have been pressure exerted by the growths on the optic nerves. Again, notwithstanding the great amount of disease discovered in the right pleural cavity after death, there were no ante-mortem symptoms beyond dyspnoea and a slight cough, which only came on about three weeks before death. In addition to these slight symptoms, at one time I detected what I thought to be a fluid effusion in that side of the chest; for there was dullness on percussion and absence of respiratory murmur at least two inches higher than a subsequent exploration revealed.

As regards the frequency of such cases, I have carefully searched through most of the English and French works on diseases of the eye and on general surgery, and have been unable to discover with certainty any similar ones. In two cases—one re-

ported by Abernethy,* the other by Paget†—the growths seemed to have been similar in their site, but neither was secondary to, or contemporary with, other like deposits. I wish to make it clear that I do not refer to recidivars after extirpation of the eyeball, for they are common. Many of the cases I have met with in my reading, especially among writers of the earlier part of this century, that have been classed as encephaloid, seem to have been really sarcomata. Galezowski refers to Nélaton's Clinical Surgery as mentioning several; but, on examining the record, they are found to be described as encephaloid. Owing to no description of their microscopical appearances being given, I think it best to pass them over.

The drawing was made about two months before death. When this took place, the morbid changes were still more marked.

REMARKS RELATIVE TO THE USE OF GELSEMINUM IN THE TREATMENT OF INTERMITTENT FEVER AND IRRITABLE BLADDER.

BY JAMES D. McGAUGHEY, M.D.,

Wallingford, Connecticut.

GELSEMINUM has been before the profession for a number of years, and, although possessing valuable therapeutic powers, has not come into general use, and does not receive the attention that should be accorded to it. I have been somewhat surprised to find that there are many physicians who have never prescribed it, and who know nothing about it. This seems to be the case more especially with country, or, as our metropolitan brethren love to term us, "rural," physicians, who with increased age get to running into routine channels, diminishing their materia medica until but few medicines are left, and continuing the use of these to the exclusion of others, because, having tried them for years, they "know what they can do with them," not realizing that certain ends which they

* Surgical Observations on Tumors, etc., p. 43. London, 1811.
† Paget's Lectures on Surgical Pathology, p. 469.

may have attained with their exclusive materia medica can be more easily, scientifically, and quickly reached by other remedies gradually coming into use. Some physicians have a particular fear of those remedies which, if taken to a certain extent, produce their physiological effects upon some particular organs or parts of the economy, and look upon those who use them, especially if younger in the profession, as audacious spirits, whose temerity will be properly tempered by age. According to my experience, gelseminum is one of those remedies whose therapeutic powers are not fully brought into play until its physiological phenomena are produced. Its remedial qualities may be exerted, though, to a certain extent, prior to its paralyzing effect upon the motor nerves of some muscles; but to be useful to its fullest extent it should be carefully given until the eyelids begin to droop. I deduced this opinion from having observed its action while using it in intermittent fever; and, this being the case, many abandon it because they derive no benefit from it, or because the unpleasant complaints of unreasonable patients more than counterbalance the good achieved. Gelseminum has been used in quite a number of diseases: lauded by some, condemned by others; of ephemeral reputation in some localities, a permanent and much-used medicine in others. I do not intend to say anything relative to its therapeutic power in any disease except two,—intermittent fever, and irritable bladder. In the latter, I have had but a limited experience; in the former, my opinions are deduced from a large number of cases. I have used it in intermittent fever *to assist cinchona in overcoming those cases that resisted bark when used alone*, and have been highly pleased with the success I have uniformly met with.

I will more particularly mention the *varieties* of intermittent fever in which I have found gelseminum most useful. Every physician who has had to deal with intermittent fever has met with cases of a regular paroxysmal form, quotidian, tertian, or otherwise, easily controlled by quinine; yet after a certain length of time the paroxysms return again and again, necessitating larger antiperiodic doses, until the alkaloid has become useful only in preventing for a short time the attack, having lost its curative powers altogether. In such cases gelseminum shows its antimalarial powers to a gratifying extent. If, after taking, as it were, a new start in the treatment of such a variety of intermittent fever, we attend to any congestion or inaction that may be lurking about the abdominal viscera, and combine quinine with *gelseminum*, and give them until the latter produces its physiological effects, the inveterate catenation of morbid action will be broken in upon without failure *in almost every case*, and there will be but little danger of *relapse until the subsequent season*. Of course it will fail to produce the desired effect in a small percentage of cases, as we claim no specifics in the regular practice.

The second variety is where, in the beginning of autumn, the malarial cases lose their regular paroxysmal form, and are characterized by irregular chills and sweats,—a partial paroxysm sometimes occur-

ring in the morning or afternoon,—occasionally alternate fever and sweating during the night; loaded tongue; *pains in the bones and joints* all over the body; headache; anorexia; nausea; high-colored urine; occasional dysenteric symptoms; malaise, etc. If quinine has been used alone in these cases without any amelioration of symptoms, the vagary of malaria still holding its curious anomalous course, gelseminum, added to the treatment and pushed to considerable weakness of eyelids, will generally conquer the disease in a short time.

Its effects in one case that came under my observation during the past season seemed more magical than otherwise; though such an extravagant term is hardly allowable in sober medicine. I feel pretty well assured that if physicians will give gelseminum a fair trial in connection with quinine, in cases where quinine alone has failed to cure, they will meet with gratifying success; provided *they push the gelseminum until its physiological effects are produced*. I think it is of prime importance, *in all cases of malarial fever, to attend strictly to the condition of the abdominal viscera*,—to keep the eliminative organs, bowels and kidneys, in a state of activity. It is to the neglect of such precautions that we are to attribute so many failures in administering quinine. I paid attention to this point in the treatment of about one hundred and twenty-five cases of intermittent fever which have come under my observation in the past two years, and I am fully convinced that if we ignore the condition of the abdominal viscera, and recklessly rely upon the antimalarial powers of quinine alone, or its accessories, the fame of cinchona as a "specific" will never be vindicated or realized.

Gelseminum has been recommended by some physicians in gonorrhœa, but I cannot see upon what grounds. It has some control over the mucous membrane of the bladder and urethra, but none at all, I think, over the specific inflammation produced by gonorrhœal virus.

Dr. W. Scott Hill, of Maine, in the *American Journal of the Medical Sciences* for January, 1872, reports five cases of irritable bladder successfully treated with gelseminum combined with bromide of potassium; but how much of the cure depended upon the bromide he does not seem to say. A relapse of Case II. "was successfully treated with gelseminum alone," says Dr. Hill; but bromide of potassium was a prominent constituent in the treatment of the other five cases (including the second, excepting the relapse). A few days ago a gentleman called upon me to treat him for gonorrhœa. After taking the usual treatment for a day or two, the discharge stopped; he took cold, and the discharge returned worse than ever; the foreskin became infiltrated, and there was great pain in making water, with considerable depression of spirits. By rest and careful treatment he improved: the discharge again stopped, but the bladder had become very irritable; he was compelled to pass water every fifteen minutes, with pain and scalding, only a few drops coming away at a time. Gonorrhœal treatment was omitted, and I placed him upon a combination of bicarbonate of potassium and morphia.

After three days he returned, and reported no improvement. I then gave him bromide of potassium, bicarbonate of potassium, fluid extract of gelsemium, a little fluid extract of buchu, and tincture of lupulin. In a day or two he was entirely relieved. While taking the gelsemium the gonorrhœal discharge *reappeared*, and he was compelled to return to injections, and to cubebs; and, as his health was somewhat impaired, and the discharge chronic, quinine, iron, and cantharides were used to complete the cure. This case corresponds with those of Dr. Hill, and further corroborates his observations as to the beneficial effects of gelsemium in irritable bladder, provided bromide of potassium has no controlling powers over the irritable conditions the urinary mucous membrane sometimes gets into. Gelsemium being so useful in irritable bladder, it seems reasonable to suppose that, combined with bromide of potassium, it would be quite an efficient agent in combating urethral fever, and in allaying the extreme sensitiveness that sometimes arises in cases of those addicted to onanism. Perhaps spasmodic stricture might be overcome by it, as its power in paralyzing the motor nerves of some muscles certainly shows it has antispasmodic virtues. Extended, cautious observation relative to the therapeutic value of gelsemium will, I think, establish it as a first-class remedy, to be depended upon in certain emergencies, answering certain indications that can be supplied by no other medicine.

ANALYSIS OF ONE HUNDRED CASES IN OBSTETRIC PRACTICE.

BY J. H. BLATNER, M.D.

CASES.

LEFT occipito-anterior	49
Right occipito-anterior	30
Placenta prævia centralis	1
Placenta prævia lateralis, complicated with shoulder-presentation	1
Lateral plane, with prolapse of hand and arm	1
Prolapsed uterus	1
Placenta accreta	4
Left occipito-anterior complicated by tumor at junction of coccyx and sacrum	1
Twins, complicated with laceration of the cord	1
Cord about neck of child	4
Face-presentation	2
Eclampsia, complicated labor	1
Constricted band from superior to inferior commissure, complicated labor	1
Hand and arm prolapsed	2
Abortion in consequence of typhoid fever	1

Total 100

Auscultation of the number of pulsations of the foetal heart, with a view of determining the sex in utero, tested in 20 cases.

Five females, pulse ranging from 135 to 180; 9 males, pulse ranging from 110 to 130: diagnosis correct in 14 cases.

PLACENTA PRÆVIA CENTRALIS.

Mrs. P., æt. 22, robust constitution, primipara. Had hemorrhages during the third, fourth, fifth, and seventh months of pregnancy. The hemorrhage being per-

sistent during the latter month, the diagnosis of placenta prævia was made. At this time labor-pains also set in, and the hemorrhage continued. Having made but little progress after twelve hours of labor, and having employed the tampon and a rubber bag filled with water to check the hemorrhage, with but little success, we concluded to dilate the os and cervix with Barnes's dilators. The dilators were used during the day, when, the os being sufficiently open to admit the passage of a few fingers, rapid dilatation was effected by means of the fingers and hand. The insertion of the placenta being directly over the os, it was almost entirely removed, and podalic version performed. Very little hemorrhage followed the operation. After the delivery of the fœtus, a small portion of placenta was found to be adherent to the inferior margin of the anterior surface of the uterus. The hemorrhage following the operation was not such as we would naturally expect with an adherent placenta. I attribute the recovery in this case to the method of treatment, viz., the rapid dilatation of the os and cervix, and the quick termination of labor, known as the *accouchement forcé* of the French writers. A few days after confinement parametritis developed itself, followed by pelvic cellulitis and the formation of a pelvic abscess. The abscess finally opened through the posterior wall of the vagina.

The remaining history of this case is that of a slow recovery. The patient is now in good health, and has since miscarried again at the fifth month of pregnancy. The complications attending the lying-in state were treated by carbolic acid injections, tonics, and a supporting regimen.

SHOULDER-PRESENTATION, COMPLICATED WITH PLACENTA PRÆVIA LATERALIS.

Mrs. G., æt. 35, robust constitution, multipara. Had at her first labor twins which were still-born, and at her second a macerated fœtus. During this, her last confinement, pains came on early, and no diagnosis of the presentation could be made during the first twenty-four hours of labor. After a siege of nearly forty-eight hours, the following condition of things was found. The shoulder was presenting at the os, and on one side the margin of the placenta could be easily distinguished. Auscultation was repeatedly employed, but it gave no clue as to whether the child was living or dead. The pelvis being somewhat contracted, and the patient fast failing in strength, podalic version was determined upon, and performed while the patient was under the influence of chloroform. After considerable trouble in turning, owing to the escape of the amniotic liquor, an asphyxiated child was delivered, but could not, however, be resuscitated.

The placenta was found to be attached low down, and partially at the inferior margin of the uterus and os internum. Considerable hemorrhage followed its removal, but was controlled by means of pressure, ergot, cold applications, etc. The patient rallied well while in child-bed, and is at present in good health. The only objection to version in this case might have been the possibility of detaching the placenta during the operation, and thus engendering a dangerous hemorrhage. But the position of the child and the late hour at which a diagnosis was made in this case admitted of no other course of procedure.

Should a similar case occur again in my practice, I would, provided I could make a diagnosis sufficiently early, employ rapid dilatation, and effect as speedy a delivery as possible, in order to save the life of the child, the cause of whose death in the case cited was undoubtedly the long-continued pressure upon the placenta and cord.

LEFT LATERAL PLANE PRESENTATION, WITH PRO-LAPSE OF THE ARM AND HAND.

Mrs. D., æt. 40, pale and anæmic, multipara. Has had six previous confinements, most of which were breech-presentations. At my first examination, which was twelve hours after uterine contractions had begun, and the waters broken, I found a hand and arm filling up the vagina, and, upon introducing my finger into the os, plainly felt the thorax of the child. By external manipulation I found the head in the left side of the mother. Examining the position of the hand, which lay with its palm towards the anterior surface of the vagina, I diagnosed a lateral plane presentation, with the abdomen of the child towards the anterior surface of the vagina. The pulsation of the foetal heart was heard on the left side below the umbilicus, and at the rate of 132 per minute. Podalic version was the only plan of treatment indicated, and it was accordingly performed with much difficulty, and only after repeated attempts. The extremities and thorax were easily brought down as far as the head, which would not yield.

Sneller's method of hooking the finger in the mouth of the child was first attempted, but, it proving unsuccessful, I employed the method generally known under the name of the "Prayne manipulation." This consists in bringing the body well down, placing the first and third fingers on the nape of the neck, bringing the occiput under the symphysis by drawing the body of the child well towards the nates of the mother, and then raising the body towards the abdomen of the mother, by means of which the forehead and face are carried over the perineum. The only objection to this treatment is the impossibility of supporting the perineum, as both hands of the operator are in use. The danger of tearing the head from the trunk, as stated by some authors, is hardly, I think, to be dreaded; in case of a macerated foetus it might possibly occur. By this manipulation I succeeded in delivering the foetus, which proved to be, as I had suspected from the foetal pulsation, a male child, with an unusually developed, although not hydrocephalic, head. The patient progressed towards convalescence without any interruption. The child, which was born in an asphyxiated condition, was resuscitated by introducing a small catheter into the larynx and thus inducing artificial respiration.

LABOR IMPEDED BY A BONY TUMOR AT THE JUNCTION OF THE SACRUM AND COCCYX.

Mrs. R., æt. 40, weak constitution; has had two previous confinements, the first of which was tedious, but terminated naturally; at the second confinement she was attended by a homœopathic physician in Brooklyn, who applied the forceps after she had been in labor for over forty-eight hours. The patient states that when the child was delivered with the forceps she felt something snap or break. At her third confinement, in which I attended her, the pains came on well, and the os dilated rapidly. Everything progressed normally until the head had fairly entered the excavation of the pelvis, when it seemed to lie impacted. Upon making a more careful examination of the bony structure of the pelvis, I found just at the junction of the sacrum and coccyx a hard resistant body, about the size of a walnut, with one end flattened, which evidently was the cause of the non-advancement of the head. Upon questioning the patient more closely, I discovered that she had sustained a fall upon her back and buttocks when 17 years of age, and was lamed in consequence for some time after. The tumor was apparently caused by the union of a fracture of the lower end of the sacrum, with resulting exuberant callus, and anchylosis of the sacro-coccygeal joint.

After consultation with Dr. Vanderveer, we decided to apply the forceps. The head, being small, was easily

delivered without any unpleasant complication. With the exception of a very lame back, the patient convalesced nicely. The head of the child bore no impression whatever, and it is to this day living and in good health.

FRAGILE CORD—LIGATURE APPLIED THREE TIMES.

On January 8, 1873, I attended, for my friend Dr. Case, Mrs. M., a healthy multipara, in her second confinement. The case was a perfectly normal one, and nothing untoward happened until I proceeded to ligate the cord, which, as is my custom, was tied about three inches from the navel. The first ligature, which was not tightly drawn, cut through the coats of the umbilical vessels, and copious hemorrhage ensued. I immediately applied a second ligature, but with the same result. The ligatures of which I had made use were composed of five or six strands of cotton thread; I have found them serviceable in most cases. Compressing the bleeding vessels with my fingers, I sent for some broad tape, and finally succeeded in ligating the cord by means of it, there only remaining about one inch of the cord attached to the umbilicus. Was this a case of fatty degeneration of the umbilical arteries and veins? It certainly demonstrates the necessity of not cutting the cord too near the navel.

TWINS AT SEVEN MONTHS, COMPLICATED WITH LACERATION OF THE CORD.

Mrs. T., a French lady, æt. 28, multipara. I was called in great haste on the 28th of June, by a message stating "that the woman was bleeding to death." When I arrived I found the patient very feeble, and almost as pale as a cadaver. The bed was drenched with blood. Upon inspection, I discovered a seven-months' foetus already born, and immediately tied the cord. Examining per vaginam, I felt the breech of a second foetus, which was not advancing, as there were no uterine contractions, and the uterus was almost in a state of atony. There being no time to lose, I extracted the second foetus, and in doing so must have lacerated the cord, for there was very profuse hemorrhage, which I afterwards found came from the laceration in the cord. The placenta almost immediately followed. The hemorrhage ceased when pressure was applied above and below the laceration, until I had an opportunity to apply the ligatures. The placenta was divided in two parts by a membranous ridge. The patient needing all my attention, I could make no attempt to resuscitate the children. The patient made a very slow recovery, and is yet suffering from anæmia.

LABOR COMPLICATED BY THE PRESENCE OF THE HYMEN.

BY E. P. BERNARDY, M.D.

ON the morning of the 8th of November, 1873, I was called to attend Mrs. E. M., æt. 20, in her first confinement. On arriving, I found the patient had suffered all the day before; the pains were not strong. On making an examination for the purpose of discovering the condition of the os, my finger came in contact with what I first supposed to be the smaller left lip of the vulva; but on directing my finger towards the right side I was able to enter the vagina without much difficulty. The os was completely dilated, bag of waters ruptured, vertex presentation in the left anterior position. Notwithstanding the pains, the head remained fixed at the superior strait.

On withdrawing my finger, I gave it a hooked shape, and when near the exit I was unable to withdraw it, on account of its being held back by a membrane, which, on exposure, I found to be the hymen. It extended from the lower back portion of the meatus urinarius along the left side of the vulva down to the fourchette, leaving a space on the right side large enough to introduce the first two fingers. The hymen was very flexible, and easily pushed towards the left side.

After waiting for nearly four hours, and finding labor had made no progress, and the patient getting weak, I determined to deliver with the forceps (Wallace). I first cut the hymen, which was done by my slipping my left index-finger under it, putting it a little on the stretch, then, running a bistoury along the finger, I cut it in half; the cut was followed by a few drops of blood; the forceps were applied, and the patient delivered of a fine, healthy boy.

The patient did well, with the exception of some irritation of the bladder, which yielded to treatment. In treatment of the cut, carbolic oil was used.

In questioning the husband, he stated that he was unable to have intercourse without subjecting his wife to great suffering, and that on several occasions he had to cease from the attempt.

I report the case, believing that it will prove interesting to your readers, as such cases are very rare.

PHILADELPHIA.

NOTES OF HOSPITAL PRACTICE.

CHARITY HOSPITAL, BLACKWELL'S ISLAND, NEW YORK.

CLINIC OF PROF. LEWIS A. SAYRE.

Reported by FRANK WOODBURY, M.D.

CARIES OF CLAVICLE AND STERNUM—SAYRE'S APPARATUS FOR FRACTURED CLAVICLE.

THIS patient (a man, aged about 28 years) has caries of the clavicle and sterno-clavicular articulation, over which there are a number of sinuses; there is also one over the middle of the sternum. He dates the disease from a bruise in this situation, caused by being "jammed" by a horse, some months ago. This is a *strumous* affection, according to some surgeons, but I consider it purely local. To me the morbid process here was as simple as that in an ordinary abscess, for which we are not in the habit of invoking a special diathesis. At the time of the injury the tissues and periosteum were contused; periostitis followed, which caused the death of a portion of bone; an abscess naturally resulted, which gradually worked its way to the surface, and the bone continued in a carious or ulcerated condition. A bone-abscess is as simple as an abscess in the soft parts, only its progress is slower.

Ether having been administered, we will now expose and scrape away all the dead material, but will leave the periosteum as perfect as possible, so as to encourage the formation of new bone. The subject of the reproduction of bone is one of great interest in conservative surgery, and has excited general attention during

the last few years by some of the surprising results that have been reported, which I need not recall to you.

The sinus over the sternum is treated in the same way. The disease is found to involve almost the entire thickness of the bone. Had this abscess opened into the chest instead of externally, the sternum would have required early trephining in order to prevent empyema and serious chest-trouble.

As the sterno-clavicular support to the shoulder is destroyed by the removal of the inner extremity of the clavicle, we will endeavor to keep the clavicle at rest until the periosteum reproduces the bone. To do this we will apply my adhesive-plaster dressing for fractured clavicle. When the clavicular brace is destroyed by fracture or disease, the shoulder falls downward, forward, and inward; the outer fragment of the clavicle (drawn down by the weight of the arm through its ligamentous and muscular attachments) is overridden by the inner portion (elevated by the sterno-cleido-mastoid). The object of every method of treatment is to force the shoulder upward, outward, and backward, and to keep it in that position. These indications can be perfectly fulfilled by two broad (three-inch) strips of adhesive plaster, about one-half yard long. The end of the first strip is doubled over and stitched so as to form a loop, a little larger in circumference than the middle of the arm. This is slipped over the arm, after being heated, so that it adheres to it around the belly of the biceps. The elbow is then pushed upward and backward, and held there while the strip is carried transversely across the back, entirely around the chest, and the end fastened to the body of the strip at the back. Now, if the elbow of the affected side is brought forward, and the hand placed on the opposite clavicle, the first loop around the arm acts as a fulcrum, and the other extremity of the humerus and the shoulder are forced upward, outward, and backward. The arm is held in this position by the second strip of plaster, which, starting from the sound shoulder, runs along the fore-arm under the elbow, and obliquely across the back to its origin, where it is fastened. By this means the deformity is perfectly reduced in fractured clavicle; and, as the same indications require to be fulfilled in this case, we will here apply it. Taking the patient by the affected arm, he can be whirled around on his heels without producing displacement or pain. With the imported plaster that I use, the apparatus does not need reapplication, but may remain undisturbed until the bone unites.

CHRONIC SYNOVITIS OF ELBOW-JOINT.

This man is a blacksmith, aged about 40. A year ago he contused his elbow, and, although it remained weak and somewhat swollen, he was not prevented from working at the anvil until ten weeks ago. Then it became inflamed, swollen, and so painful as to deprive him of rest at night.

It may eventually be necessary to excise this joint; but in the mean time, as the fore-arm and hand are cedematous and congested, we will try what can be gained by emptying the capillaries by pressure and applying cold. The elastic bandage will unload the blood-vessels, and, if the morbid process has not advanced too far, we may save the joint.

This gum bandage, if applied only around the elbow, would quickly strangle the limb, and cause mortification by obstructing the circulation. In order to avoid this, we apply it regularly up from the hand (having the fingers first separated by cotton wadding), so as to equalize the compression. The joint will now be surrounded by an ice-poultice, to keep down heat and inflammation, and he shall have anodynes, and a supporting treatment. As there is no disease of the articular cartilages, extension is not required.

HIP-JOINT DISEASE—SAYRE'S APPARATUS.

This boy has trouble in his hip-joint, with great deformity: as his mother speaks but little English, and he none at all, it is impossible to gain a satisfactory history of the case. He is rather old for true hip-joint disease, and I am in doubt whether it was not originally a diastasis. However, you shall hear the few notes of his history that we have been able to obtain. He is a Dane, about 15 years of age. He was a strong, healthy child until ten years ago, when he commenced to limp; this was followed by an abscess in the hip-joint, which still discharges through several sinuses. His mother is positive that he received no injury at that time; but she may be mistaken, as children are often crippled by a nurse's carelessness, while the mother remains ignorant of the cause.

In order to estimate the deformity in a case of hip-joint disease, place the patient straight on his back on a table or the floor; then, having an imaginary line drawn parallel with the iliac crests, at right angles with the axis of the spinal column, and the sound leg extended, the distortion is apparent. Applying this to the case before us, we see the affected thigh lying across the abdomen with the knee above the opposite iliac crest,—an impossible position if the joint was normal. As he resumes the erect position, the pelvis "cocks up like a duck's tail" in the effort to accommodate itself to the disease, and the deformity is less marked.

There has been serious destruction of this joint, and the constant suffering and discharge have greatly affected his general health, and, if unrelieved, would undoubtedly cause his death. He is anæmic, and apparently broken down by the disease; yet he will bear the suppurating and shock of the operation really much better than his appearance would indicate, from the fact that the system has in a measure begotten a tolerance of the disease and endeavored to accommodate itself thereto.

It is of great importance to recognize hip-joint disease in its incipient stage, so as to give it the advantage of treatment as early as possible. Two principal points in the diagnosis are pain and position. The pain complained of is intermittent, may be felt anywhere along the limb, but is most frequently referred to the knee, and often attacks the patient suddenly at night. This is produced by the sudden, forcible impact of the diseased articular surfaces, caused by reflex spasmodic contraction of the hip-muscles, from the irritation of the nerve-filaments terminating in the diseased tissue. And this may be taken as a hint for diagnosis. If the joint is inflamed and painful, you can relieve the sufferer at once by simply making extension at the heel; if, on the contrary, you press the diseased articular surfaces together, you elicit unmistakable evidences of pain.

Now, as regards position. In the natural joint the fibres of the capsular ligament, especially that part of it known as the Y or ilio-femoral ligament, run obliquely across the joint. When the capsules become distended by effusion, it can only accommodate itself and increase its capacity by untwisting; this rotates the thigh outward, and slightly lengthens the limb. In this, which may be termed the stage of effusion, the toes are everted, and the heel of the affected limb presents towards the opposite instep. When the disease advances farther, the capsule becomes ruptured, and the effusion escapes; but if the bone becomes extensively diseased it may be gradually disarticulated, and rides on to the dorsum of the ilium; and you will then have the deformity accompanying the iliac dislocation, rendered more marked by the destruction of bone and atrophy of the muscles.

When there is pus in a joint, accompanied by destruction of the synovial membrane, there is no more dan-

ger in opening the joint than in evacuating an abscess in any other situation. The destructive process may sometimes be checked in hip-joint disease by liberating the pus early and applying extension.

The patient being etherized, I will make a free horse-shoe incision around the great trochanter, directly down to the bone. I will not make a careful dissection of each layer of tissue, and divide them upon a grooved director, because by so doing I should make a number of leaflets by which pus could burrow and dissect the neighboring structures; but, selecting a point midway between the edge of the trochanter and the crest of the ilium, I plunge the knife directly into the joint. I find the head and neck of the femur entirely gone; the trochanter minor is eroded and altered by new bony deposit. The acetabulum is good. I will now make an incision through the periosteum, and peel it carefully from the bone. We will now remove the head of the femur below the seat of the disease, being careful not to disturb the insertion of the *psoas magnus* and *iliacus internus* in the periosteum in front,—a point of great importance as regards the future usefulness of the limb. In order to straighten the leg we are obliged to cut the tendon of the tensor *vaginæ femoris*, which, from the distortion, is immediately over the femoral artery. The tendons of the adductor and *gracilis* must also be divided close to their origin. The tenotomy, which should not terminate in a point, but in a cutting edge, is passed behind these muscles, then turned forward so as to shave them from the bone. I will encourage immediate union between the walls of the chasm thus made, and prevent an abscess, by pressing them together by an adhesive strip.

We will not close the wound on the hip, but allow it to remain open for two days, in order to encourage the discharge of pus and prevent infiltration, which we will further guard against by making pressure along the lips of the wound by adhesive strips. The wound shall be packed with sponge, and the periosteum kept distended until bony deposit takes place. The wound is dressed with Peruvian balsam, which, as it contains creasote, is a disinfectant; and I prefer it to carbolic acid because it is far more agreeable.

Rest for the joint is now imperative until the time comes for passive motion, which will prevent ankylosis and make it an ununited fracture. By some surgeons the patient is kept in bed with extension on the leg, but by my apparatus—the "wire breeches"—the object is attained without confining the patient to bed or to the house, as he can go out and get the fresh air every day,—a great advantage to these broken-down subjects of a chronic disease. The apparatus consists of an iron-wire frame-work to support the body and legs, with a movable head-rest, and two foot-plates working by screws, so that strong extension may be maintained when they are fastened to the feet. Lateral strips of plaster run up the inside and outside of each limb, and are then attached to the foot-plates. If extension were made from the foot only, it would strain the lateral ligaments at the ankle. Some oakum being placed in the perineum to relieve the pressure, the pelvis is fastened by a roller bandage, which, running through the perineum and fastening to the side of the apparatus, serves to make counter-extension. Having the foot-plates attached, a folded newspaper is laid over the sound knee, and the limb surrounded by a roller bandage, so as to prevent it from bending and convert it into a solid column of support for the pelvis. The affected limb is now screwed down until it is straight, and we find a shortening of nearly four inches. The extension will be gradually increased as the fascia stretches and the stiffened tissues yield. The pelvis has so long been held at an angle with the spine that it refuses to straighten immediately; but we will put in a

wedge of pillows under his back that can be gradually reduced. The patient now requires good nursing and careful attendance; the wound should be dressed several times a day, if necessary. This can be done without changing the apparatus, which may remain indefinitely. He shall have an anodyne immediately, and good food, cod-liver oil, and stimulants.

Here is a little girl,—a similar case,—operated upon nine weeks ago. She now walks on crutches. There is considerable motion in the joint, as she can lift her foot to put it on a small stool, and, by stooping, flex the thigh at right angles to her body.

TRANSLATIONS.

INFLUENCE OF THE VENOM OF CROTALUS HORRIDUS UPON ELEPHANTIASIS.

From the Portuguese "*Diccionario de Medicina Popular*, por S. L. N. CHERNOVIZ, M.D., Rio de Janeiro, Brazil."

ACCORDING to vulgar belief in many of the States of South America, where elephantiasis is very prevalent, the bite of the rattlesnake is a certain cure for that fearful disease, without any disastrous consequences to the patient. Rumors of cures made by this means came to the ears of a poor-unfortunate who was suffering from the affection, and he determined to try it.

His history is given, in the hope that it may destroy confidence in so unscientific a procedure, and deter any one from an experiment that would be perilous, if not fatal, to life.

Mariano José Machada, æt. 50 years, a man of medium size and athletic constitution, a native of the province of Rio Grande do Sul, Brazil, was attacked by elephantiasis in its severe form; and it made such rapid progress that he was soon disabled and obliged to enter the Lazarus Hospital, in the city of Rio de Janeiro. Here he remained a helpless invalid during four years, subjected to every manner of treatment, without the least improvement in his condition. The disease had extended over his entire body. The skin was everywhere brawny, fibrous, and hypertrophied. The subcutaneous and adipose tissues were increased, and tuberculated lumps were scattered over the body. In the axillæ many of these had ulcerated, and discharged a sanious pus, mixed with shreds of degenerated tissue. The dartos was hypertrophied and hard. His face presented a horrible deformity. The extremities of his fingers had lost their shape; their epidermis could be easily separated in shreds, and the nails were so altered as to be unrecognizable.

Suffering constant pain, a loathsome object, despairing of relief, hating a life so burdensome and dreadful, he caught at the slender hope offered in the reports which reached him, and resolved to ameliorate his condition or die.

The hospital physicians explained to him the uselessness of the remedy proposed, pointed out the certain fatality of it, and endeavored to dissuade him from his determination; but in vain.

He said he was tired of living, and would submit himself to the ordeal, whatever might be its result. He made a statement to the people, and signed a declaration that he acted by his own free will against the advice of his physicians, and that he himself assumed all the responsibility.

Accompanied by his medical attendants, and by a great multitude of people attracted by the novelty and desperation of the proposed act, he proceeded to Rua da Imperatriz, No. 61, where a gentleman had a large rattlesnake in a cage, and, passing his right hand into it, seized the snake around the body. The animal

turned its head and rubbed its nose against the hand upon him. Mariano then tightened his grasp, and the snake buried its fangs in his finger.

This occurred at 11.50 A.M. on the 4th of September. He did not then feel any sensation from the bite, nor from the poison introduced into the wound, and only recognized that he was bitten by the drops of blood upon his finger, and the swelling which soon supervened.

Five minutes after, he experienced a sensation of cold in the hand; and ten minutes later, he felt a slight pain in the palm.

At 12.30 P.M. his hand had increased in size, and the pulse beat much stronger.

At 12.50 his sight became dim, he experienced considerable itching about the face, the volume of the hand was greater, and the pain had extended up the forearm.

At 1 o'clock he was seized with trembling over the entire body, and there was great hyperæsthesia.

At 1.36 the hand was greatly swollen, the fore-arm somewhat enlarged, the pain had extended to the shoulder, there was difficulty in moving the lips, with a sensation of choking, the pulse was more frequent, somnolence manifested itself, and the intellect was profoundly disturbed. Soon after, he complained of feeling cold, and covered himself up with the bedclothes.

At 1.48 he had pain in the tongue, which extended to the throat and stomach.

At 2 o'clock there was difficulty in articulation, and twenty minutes later of deglutition, accompanied by anxiety; there was copious perspiration upon the anterior surface of the body.

At 2.38 the pulse was 96 beats in a minute, there were much restlessness and prostration, and epistaxis commenced.

At 3.5 there were great pain in the arm and face, general perspiration, continuous nasal hemorrhage, and involuntary groaning.

At 3.35 the patient swallowed wine and water without difficulty, though he felt much pressure in the throat; the respiration was labored, and his acute pain did not permit any rest. The nasal hemorrhage continued, and several pustules in the right axilla began to bleed. The arm had become much darker in color, and a redness had become diffused over the entire surface of the body.

At 4.50 his pulse was 104, the temperature of his skin was much above the normal, and saliva dribbled freely from his mouth.

At 5.30 he passed an abundance of urine.

At 7 o'clock the patient slept, groaning continuously, and soon after awoke with a severe pain in his breast and a sensation of choking. Had a copious evacuation of urine. The hemorrhage still continued. He was given aguardente,* water, and sugar, but could not swallow.

At 9.30 he was in a deep, quiet sleep.

At 10 o'clock he took three tablespoonfuls of an infusion of guaco,† and at 11 he took four more of the same.

At 12 P.M. he was sleeping, and apparently comfortable.

At 12.30 A.M. the patient awoke in great alarm, shouted wildly, and wished to confess to the priest. Continued to take the infusion every half-hour. His symptoms for the remainder of the night were much the same. Nasal and pustular hemorrhage continued; he had much pain, was restless, would sleep a little and then awake in great alarm.

At 9.45 A.M. blood appeared in the urine; there were great prostration, and convulsive movements of the throat and lower extremities.

* Aguardente, the common spirit of Brazil, distilled from the fermented juice of the sugar-cane.

† Guaco huaco—the name of a plant indigenous to South America, called *Eupatorium guaco*, order Compositæ: used by the negroes as a specific for snake-bites.

At 10 o'clock a large sinapism was applied to the inner surface of each thigh; he was given an enema of arguente and water, and by the mouth $\frac{1}{3}$ i of lizard oil.

At 11.30 he became comatose, and died quietly. His body was livid in color, covered with purple ecchymoses, exhaled a most offensive odor, and soon swelled to a great size.

G. T. PIZA E ALMEIDA, Student, and
W. H. WINSLOW, M.D.

743 SOUTH TWENTIETH STREET.

ANÆSTHESIA OF THE RETINA.

DR. HIRSCHLER (*Wiener Med. Presse*) calls attention to the fact that, although a large proportion of cases of amblyopia and amaurosis have been explained by the use of the ophthalmoscope, there still remains a considerable number of cases of blindness for which no adequate solution has yet been given. Among these he mentions cases of so-called anæsthesia of the retina, and calls attention to the loss of sight occurring in feeble and hysterical patients. He mentions also those cases of amaurosis which occur suddenly after emotional excitement, or are due to traumatic causes.

A short time ago Dr. Hirschler had the opportunity of observing the case of a woman aged 40 years, who had been injured in the eye by the explosion of a percussion-cap. Immediately after the receipt of the injury, the patient felt pain in the eye, accompanied by the sensation of strong light. The next day she noticed that she was blind in the left eye, and presented herself to the doctor. Nothing abnormal could be seen about the eye, with the exception of a high degree of short-sightedness and strongly-contracted vessels, nor did the patient complain of any pain. If a lamp was held before the eye at a distance of two inches, she was able to see a small point of light; but with this exception she was totally blind. Four days later, the patient was able to see the flame of the lamp at a distance of ten inches, but in other respects her condition was unchanged. In the treatment of the case hypodermic injections of strychnia were employed, but were soon discontinued, owing to the occurrence of symptoms of strychnia-intoxication. Nine days after the accident, a slight improvement was noticed, which steadily increased.

On the 15th of November, about a month from the time of injury, the patient could read Jaeger No. 4, and was regarded as entirely recovered. This case was regarded as a very instructive instance of "anæsthesia retinæ traumatica," and the contraction of the retinal vessels, alluded to above, played an important part in the production of the blindness. The contracted state of the vessels was due to cramp of the muscular tunic excited by the injury. The improvement which was noticed was due not to the influence of the strychnia, but to the remission of the contraction of the muscular tunic.

WILLIAM ASHBRIDGE, M.D.

THE ACTION OF BROMIDE OF CALCIUM.

ACCORDING to the statements of Hammond (*Berliner Klin. Woch.*: Guttman), the bromide of calcium displays more activity in its action in nervous diseases than the bromide of potassium, because it is more readily decomposed, and thus furnishes free bromine more quickly. This last inference can scarcely be supported, since Guttman and Eulenberg have already demonstrated that the action of bromide of potassium is

not due to the bromine which it contains, but to the potassium, and that it operates in the same way as the other potassium salts. The bromide of sodium, on the other hand, has a different action from the bromide of calcium, since it manifests the same powers as the other sodium salts,—a conclusive proof that the bromine is not the active constituent in the salts under discussion. These experimental results are confirmed by the therapeutic use of these salts, the cheaper chloride of potassium being substituted for the more costly bromide. Bromide of calcium is three to four times less active than bromide of potassium, it requiring the injection of one-fourth gramme of the lime salt to kill a frog, while eight grammes were needed to produce the like result in a rabbit. The fatal results manifested themselves more slowly than after the smaller doses of the bromide of potassium,—two to four grammes of the last-named salt producing death in a rabbit in thirty minutes, while, with eight grammes of the bromide of calcium, death occurred only after several hours. The animals died with the symptoms of a gradually increasing collapse.

The evidences of the poisonous action of the potassium salt are of an entirely different character: the animals die with symptoms of paralysis of the heart, dyspnoea, convulsions, and symptoms of suffocation. The action of this salt upon the heart in warm-blooded animals is so marked that its effect upon the nervous system is scarcely noticeable. The bromide of calcium, on the contrary, does not act at all upon the heart, but upon the nerve-centres, and to a much less degree than the bromide of potassium. The iodide and chloride of calcium act in exactly the same way as the bromide.

It can then be stated, in summing up the facts relative to the action of these salts, that the bromide of calcium acts as do the other calcium salts, and that the bromine is not the active element.

The bromide of calcium is, like the bromide of potassium, a sedative to the nervous centres, but is much weaker, and if it is to be used in therapeutics must be given in much larger doses.

WILLIAM ASHBRIDGE, M.D.

CONDITION OF THE UTERUS IN PROSTITUTES.

SEYDEL gives (*Berliner Klin. Woch.*) the following results from examinations made upon 160 prostitutes:

1. The gynaecological affections of women of this class are, for the most part, affections of the uterus and the urethra (especially of the orifice of the urethra).
2. Catarrhal affections of the mucous membrane of the uterus are the most common, then inflammatory enlargement of the uterine tissues; while parametritis and changes in the position of the womb are less frequent.
3. In the urethra the most frequent pathological change is at the orifice, and is due to gonorrhœal infection and mechanical violence.
4. The discharge from the mucous membrane of the vagina and uterus is the cause of the infrequency of conception and of the frequent occurrence of abortion in women of this class.

WILLIAM ASHBRIDGE, M.D.

HYPODERMICS OF WHISKY (*Medical Record*, February 16, 1874).—In a case of shock from railway injuries, the patient was treated with hypodermic injections of from fifteen to thirty drops of whisky, his pulse being sufficiently strengthened in this manner to warrant amputation of the leg.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 7, 1874.

EDITORIAL.

HERE AND THERE.

IN America, when a young medical man whose enthusiasm has not yet been rendered torpid by the frosts of professional indifference or exhausted by the struggle with circumstances desires to do any original experimental work, he seeks out some hidden stable-loft, or perhaps by good luck obtains a corner during the summer months in some dissecting-room; and, it may be, going without his dinners to acquire the means for the purchase of his simple instruments, works away as best he can. Supposing his talents equal his enthusiasm, and that a fair measure of scientific success reward his efforts, what is the result? He has, perhaps, the satisfaction of seeing his articles quoted abroad approvingly; but at home grave professors look upon him pityingly or perhaps sneeringly; middle-aged brethren, remembering still the days of their youth, say that he will get over it; and, whilst others of his class float easily with the tide into competence and comfort, he struggles and works all the time against the rapids.

Some years since, we heard a professor in a leading medical school—a man, as measured by our standards, deservedly foremost in his profession—say to a young physician, “Doctor, I was like you when I was young: I worked hard, my papers were very well received, but I found that it did not pay. What do you get for it? Who cares any more for you? You will carry it on till you are thirty or a little older, and then you will be like the rest,—you

will give it up.” The career of the professor has been the reflex of his words,—an industrious, fruitful youth, many years of absolute barrenness in the professorial chair; and his words were the words of wisdom, his acts the result of a profound appreciation of the drift of the times, and of the means of securing the rewards valued of men.

The youth, as we watched him during the conversation alluded to, looked on with incredulity and wonder; but on talking with him recently we learned that he too had drunk of the waters of Marah and found them bitter, and we greatly fear that an election to a professorship is all that is needed to turn his steps into the trodden path and to teach him the refrain,—

“Ah, why

Should life all labor be?

Let us alone. Time driveth onward fast,

And in a little while our lips are dumb.

Let us alone.

All things have rest, and ripen toward the grave

In silence; ripen, fall, and cease.

Give us long rest or death—dark death, or dreamful ease.”

In a late number of the *Edinburgh Medical Journal* is an account of the Physiological Laboratory under the care of Professor Ludwig, at Leipsic, an account which we commend to the attention of those who wonder or are annoyed at the little recognition that American scientific medicine receives abroad. The laboratory is built so as to surround three sides of a rectangle, with a court-yard in the centre, and is about one hundred and twenty feet in each direction. It is furnished with various rooms for chemical, histological, and physiological work, with an aviary, frog-ponds, stables, rooms for small animals, etc., etc.: all necessary apparatus, from a steam-engine to prepare blood-serum, to a table and automatic respiratory bellows for curarized animals, is in profusion.

Here students are received, and after a little training are put to work under the direction of Professor Ludwig, who is thus enabled to multiply, as it were, his hands, and thereby do far more justice to his brain-power than if he had to work out all his ideas himself. The result is already seven goodly volumes of valuable researches,—a result which alone is more than America has produced in the century.

If we omit Brown-Séquard,—a cosmopolitan bird of passage,—Leipsic, a town about the size of Providence, contributes to the world in a single year more in physiology than is worth the looking at than does America in a decade. Not because the German intellect is superior to the American, but because the Germans elect professors who are workers, and would eject as a *lusus naturæ* one who did not

continue to work whilst holding his position; and because the Germans encourage young men, and give them training and opportunities for work and guidance in their early flights.

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—On p. 325 of your last issue I find a phonographic report of some remarks I was kindly permitted to make before a meeting of Philadelphia physicians a few days ago. As I had no opportunity of seeing the manuscript of the reporters, a number of mistakes have unavoidably crept in. Thus, "Dalton, of Holland" ought to read, D'Alton, of Halle; "Braun," Boehm; "embryo," amnion; "Kernoch," König. If I had a right to expect that my extemporaneous remarks on that interesting occasion could command anything but a temporary attention, I should also have desired to add a few corrections in regard to facts stated by me. For the moment, I trust you will be so kind as to insert the above changes.

Yours, very respectfully,

A. JACOBI, M.D.

110 WEST 34TH STREET, NEW YORK, February 24, 1874.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JANUARY 8, 1874.

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

DR. C. B. NANCREDE read the history of a case of *sarcoma*, for which see current number of the *Times*.

Dr. J. E. MEARS presented a specimen of a heart showing marked *disease of the mitral and aortic valves*.

The specimen was removed from a patient of Dr. R. Taylor, with whom Dr. MEARS saw the case in consultation.

The patient had been confined ten days previous to the attack. On that day she was exposed to cold, and symptoms of pulmonary congestion rapidly manifested themselves. The heart's action was markedly increased, the pulse attaining 130 beats per minute.

On auscultation, *no mitral murmur* could be detected. The pulmonary sounds and the extremely rapid movement rendered the aortic murmur very indistinct,—almost inappreciable. Arterial sedatives were employed without effect, as well as remedies both internal and external to relieve the congestion; the patient dying on the second day of the attack, from exhaustion.

Post-mortem examination revealed disease of both mitral and aortic valves. A mass, apparently of vegetations, covered the auricular surfaces of the mitral valves, leaving an opening between the auricle and ventricle about the size of a crow's quill. The nature of this mass was not determined by microscopic examination. The aortic valves exhibited structural changes, but to a much less extent.

A question of clinical interest presented itself in reference to the absence of a mitral murmur, with the valves in the condition observed, and with the extremely rapid action of the heart.

Dr. O. C. ALLIS presented a specimen of *intra-capsular fracture of the femur*, occurring in a female 77 years of age, who had fallen on the sidewalk. The usual symptoms were present, though crepitus was too indistinct to be of value in diagnosis.

The person survived the injury but fourteen days.

The specimen represents the fracture as being, *in front*, about half an inch above the *anterior inter-trochanteric line*; *behind, midway of the neck*. A reflection of the capsular ligament posteriorly holds the head of the bone to the shaft.

Dr. JAMES TYSON presented the specimens from a case of *advanced mitral disease of the heart, conjoined with disease of the kidneys*, derived from a married woman, aged 34, who died under his care at the Philadelphia Hospital. There were ascites, general oedema, and abundant albuminuria on admission, accompanied by oil-casts. The albuminuria and casts disappeared under treatment, but the signs of cardiac disease continued, and, although the oedema diminished, much of it remained. She died of acute intercurrent pleurisy with effusion, previous to which there had been no hydrothorax.

On post-mortem examination the mitral leaflets were found to have coalesced, forming a mere button-hole opening, the edges of which were rigid from calcareous deposit, and therefore incapable of closure.

The epithelium of the convoluted tubules was in many places fatty, but in others only slightly altered.

From the history of the case, the extent of the disease, and the abatement in the renal symptoms, as well as the somewhat limited degree of the alterations in the kidney, the doctor thought the cardiac disease primary, and the renal affection secondary.

A full report of this case, which contains many points of extreme interest, will be published in a clinical lecture in a later number of the *Times*.

The PRESIDENT said that such extreme degrees of mitral obstruction from coalescence of the leaflets of the valve comparatively rarely make their appearance in adult life. More frequently the symptoms show that the lesion dates back to an early age, and it is probable that in some cases it may arise during fetal life.

In regard to the absence of albuminuria during the latter part of the case just reported, he referred to an autopsy made the day previous on a patient whose clinical history presented some points of resemblance. The man was about 70 years of age, and presented evidences of eccentric hypertrophy of the heart, with slight insufficiency of the mitral valve. This was associated at various times with oedema, ascites, and hydrothorax. Paracentesis of the chest had been performed with very great relief, which lasted over eighteen months.

For a period of four years, during which the patient was under his observation, there was never evidence of albuminuria. From the appearance of the man, however, and the fact that he was passing large quantities of urine of low specific gravity, the existence of a contracted kidney was suspected. At the post-mortem examination there was found advanced cirrhosis of both kidneys, which had never revealed itself during life, except by the symptoms mentioned above.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, JANUARY 28, 1874.

DR. JOHN SWINBURNE, PRESIDENT, in the chair.

ACEPHALOUS MONSTROSITY.

DR. L. R. BOYCE presented a specimen of an acephalic monster. The woman who gave birth to it is the mother of five children. She had also aborted

once from ill health, probably due to hard work and exposure.

The present foetus was cast off at the seventh month. The ill health of the mother commenced two or three years ago, and has continued to the present time. She was in labor two and a half hours, passing through it without difficulty.

The foetus presented a lack of development of the head, the brain being wanting. There is also a spina bifida and hare-lip. The cause for this undeveloped condition was sought in defective nutrition, due to the poor health of the mother.

Dr. LEVI MOORE remarked that he had a similar case several years ago. The parents were both healthy, and healthy children have been produced by them, both before and since the birth of the monster.

Dr. THOMAS BECKETT said that he had also met with a case of the same nature. In his case there was an enormous secretion of the liquor amnii,—a bucketful. The same has been observed by others, and the cause of the monstrosity has been looked for in an abnormal condition of the amniotic membranes.

RUPTURE OF THE HEART.

Dr. LEVI MOORE presented a case of rupture of the heart.

The patient had been subject for many years to stricture of the urethra, rendering micturition slow and painful. Four weeks before his death he began to suffer severe pain in the left side and shoulder, which was aggravated by exercise. He had also occasional attacks of dyspnoea. No organic lesion of the heart could be detected. Anodynes, nutritive diet, and absolute rest improved his condition for a time. After taking a short walk he experienced great fatigue and a return of pain; and, after passing a restless night, he died suddenly while seated in a chair.

At the autopsy there was found a rupture of the left ventricle, near the base. The pericardium was distended by a large clot and about six ounces of serum. The tissue of the heart was pale and flabby. The right pleural cavity contained sixteen ounces of serum.

Dr. MOORE mentioned the various causes and conditions of rupture of the heart, and remarked that while rupture in most cases takes place suddenly, causing immediate death, in others, of which the one presented seems to be a specimen, there is a gradual yielding, going on for weeks, until rupture finally becomes complete.

Dr. BECKETT mentioned a case of rupture of the heart occurring in the person of a man who had always been healthy, and was found dead in bed, no extraordinary muscular exertion having been made. The rupture occurred in the right auricle, and the valves were almost completely calcified; his age was 50.

Dr. JOHN V. LANSING presented a case which he had recently met with; the patient, a man aged 74, who had been previously in good health, was taken at four o'clock A.M. with præcordial pain and dyspnoea, the pain passing down both arms to the fingers. Ether, carbonate of ammonia, and hypodermic injections of morphia were administered. He died next day while at stool. A large rent was found an inch from the apex of the right ventricle. There had been an apoplectic effusion about the point of rupture. The coronary arteries were atheromatous, and one was involved in the rupture. The heart weighed two pounds, and its tissues were fatty. It was invested by a firm coagulum.

It would seem in this case that the heart began to give way when the first symptoms came on. What was the cause of the rupture? It is usually associated with violent exertion, which could not have been the case here. Can it not take place from muscular contraction of the organ, a fatty condition being presupposed?

What is the cause of death in rupture of the heart? Is it pressure on the organ, or shock, or loss of blood from the circulation? All would seem to contribute in causing death.

The heart is sometimes subjected to great pressure by pericardial effusion without fatal issue.

Dr. LANSING remarked the fact that there was no serum, but simply a firm clot in the pericardium. In all the cases he had seen, the same condition was found.

Dr. C. D. MOSCHER spoke in regard to the cause of death in rupture of the heart: he mentioned a case of rupture of the aorta within the pericardium, in which the blood was probably escaping into the pericardium for about ten hours. The patient, having eaten freely, was taken with a disagreeable feeling and with pain, which were ascribed to indigestion. When seen, a few hours before death, he was laboring under dyspnoea, nervous excitement, exhaustion, and syncope.

A quart of solid and fluid blood was found in the pericardium, practically obliterating all the cavities of the heart. The interference with the action of the heart, and the loss of so large a quantity of blood from the circulation, were quite sufficient to cause death.

Dr. JAMES S. BAILEY also reported a case of *rupture of the heart*.

It occurred in the person of an elderly female. She had been affected for years with dyspnoea on exertion. Twenty-eight hours before death she was taken suddenly with syncope, and complained of a tearing sensation about the heart. Her countenance was blanched; pupils dilated; pulse scarcely perceptible, and no heart-sounds distinguishable; skin cold. There was found a rupture of the ascending aorta, half an inch above its origin; the internal coat being first perforated and dissected up a short distance before tearing through of the external coat took place. There was about a pint of solid and fluid blood in the pericardium.

Dr. VANDERVEER also reported a case which was very similar; the inner and outer coats of the aorta being ruptured in like manner at different points, and dissected up. He gave the details of another case, in which there was rupture of the left ventricle near the base. The patient, having felt perfectly well on rising in the morning, was taken with severe abdominal pain following the use of an enema to which he was accustomed. While suffering from this he was taken with pericardial pain, and died suddenly.

A third case, like the second in many respects, was also detailed.

Dr. J. H. BLATNER then read a paper on Cases in Obstetric Practice. (See Original Communications, p. 356.)

Dr. JAMES L. BABCOCK presented a somewhat unusual case of passage of a large piece of bone per anum. It came under his notice at the Almshouse Hospital, in a man coming from a distance, who claimed to be suffering from piles. He was very weak, and could not walk. Upon examination, he found the parts swollen, inflamed, and tender. Upon introducing his finger, he felt a hard body, which he succeeded in withdrawing. It was a piece of bone one and a half inches long by half an inch wide, which had become lodged in a cul-de-sac above the sphincter ani.

COLOR-TEST FOR CHLORAL HYDRATE.—If we agitate chloral hydrate with essence of mint, the mixture becomes rose-color, and by degrees a deep red. Boiling does not destroy this color, and sulphuric acid renders it even more intense. M. Carl Jehu says that neither the other oxygenated essences nor the simple hydrocarbons produce this reaction.—*Medical Press and Circular*.

REVIEWS AND BOOK NOTICES.

HISTORY OF THE AMERICAN AMBULANCE ESTABLISHED IN PARIS DURING THE SIEGE OF 1870-71; TOGETHER WITH THE DETAILS OF ITS METHODS AND ITS WORK. By THOMAS W. EVANS, M.D., etc. London, 1873.

The American ambulance during the French war was simply a tent-hospital, in which were treated during the entire period two hundred and forty-seven surgical and twenty-four medical cases. When we first compared this record with the goodly quarto of nearly seven hundred pages, we involuntarily exclaimed, "Behold how great a matter a little fire kindleth!" As, however, it certainly is allowable for the man who has honestly earned his fortune to spend a portion of it in raising to himself monuments of paper and ink, we find no fault with the author, who has intrusted to the Chiswick Press that task which others assign to the sculptor's chisel or the painter's brush. Indeed, we congratulate the doctor upon the wisdom of his choice, for in the fragile material of a quarto the modern arts furnish that which shall last when the granite has crumbled into clay or the bronze has been corroded into shapelessness. We do not mean to deny value to the book. Just as some of the fairest creations which have ever shot new rays of beauty across the world have been due to the longing for immortality of some one poor in genius but rich in pelf, so may the printed monument have much of literary and scientific value. In looking into the book, we find that Dr. Evans differs from most of those who seek immortality at the point of the chisel, in that he has himself made at least the pedestal upon which his monument rests, since one hundred pages out of the seven hundred are partially his pen.

Space is wanting us to follow the fortunes of the really most praiseworthy efforts of the noble band of Americans to relieve the frightful suffering of the siege. Taking upon themselves the unknown perils of war, and, it might have been, of assault and sack, enduring privations, performing great and unpaid labors, risking their lives freely in the van of the battle,—they deserve the epitaph which is said to rest upon a tombstone of an American volunteer in Greenwood Cemetery: "The only son of a widow. 'She hath done what she could.'"

After examining the record, we judge that Dr. Evans bore the same relation to this work that he appears to have done to the volume before us: he largely *paid* for it, *i.e.*, for the medicines and running expenses. Certainly the sad days of the siege were spent by him in "Merrie England;" he having accompanied the Empress Eugénie in her flight, and "lingered in London" when the air was full of dark, unwholesome rumors of coming doom for the heroic city of Paris. Why should the prince of dentists risk that person and those fingers which had hung over and carved the molars, incisors, and premolars of so many crowned heads? Certainly this precious personage should be preserved at all hazards. Dr. Evans was wise. Dr. Evans was right.

The body of the book is made up of a well-written, very learned, and elaborate essay, by Dr. Edward A. Crane, upon the history and functions of army hospitals, and the use of tents: an essay which would have been a most excellent work in the antediluvian times, when a man could afford to dawdle one hundred years over the life of a gnat, but which at present would be improved by that minifying-glass known as an abridgment.

In concluding our brief notice of this monument to the aristocratic American dentist, we remark that the Chiswick Press has done its work well: the clean type,

black English ink, fine paper, and wide margins are all that even Dr. Evans could wish.

THE STUDENT'S GUIDE TO SURGICAL ANATOMY. By EDWARD BELLAMY, F.R.C.S. Philadelphia, Henry C. Lea, 1874.

This book, as stated by the author in his preface, is intended for the use of advanced students, either as a guide for operative surgery, or for candidates for medical degrees who need to refresh their anatomical knowledge previous to final examinations. The work is only a compilation, but contains much valuable information in a concentrated form. More distinctness in some of the illustrations would have added to their value.

DU TRAITEMENT DES RÉTRÉCISSEMENTS DE L'URÈTHRE PAR LA DILATATION PROGRESSIVE. Par T. B. CURTIS, of Boston, Mass. Paris, J. B. Baillière et Fils, 1873.

In this essay, to which was awarded the Civiale prize for the year 1872, Dr. Curtis enters most freely into the subject of the treatment of stricture of the urethra by gradual dilatation. His observations were made while he was a pupil of M. Guyon, and at the close of his essay are given full notes of seventy cases of stricture treated by progressive dilatation. After defining the various methods of dilatation, giving the indications and contra-indications for the use of this method of treatment, and stating the complications likely to arise during its use, Dr. Curtis gives the following conclusions:

1. Progressive dilatation is a satisfactory method for simple stricture not of traumatic origin, in which no previous treatment has been employed.
2. It is almost absolutely without danger.
3. Its average duration—twenty-eight days—is not much above that of other methods, especially if the time devoted to preparatory and consecutive precautions is taken into account.
4. It does not confine the patient to bed.
5. Relapses are not more frequent than after other methods.
6. As the cure by this method is a gradual one, it is not applicable to those cases in which there is urgent need to re-establish the flow of the urine.
7. In cases of irritable or elastic strictures this treatment is not applicable.
8. Chronic alterations of the kidneys usually offer a contra-indication for this treatment.
9. The treatment of stricture by permanent dilatation is not a method which is generally applicable.

PRESERVATION OF ORGANIC SUBSTANCES BY MEANS OF FUCHSINE.—Gelatin putrefies with the greatest facility at a temperature of twenty-five degrees, forty-eight hours only being required for it to become covered with mould, to liquefy, and undergo complete decomposition. If to a solution of gelatin is added a fifth part of fuchsine, it can be preserved in the open air during an indefinite period. A piece of beef weighing fifty grammes has been enveloped in blotting-paper moistened with a solution of a hundredth part of fuchsine. This piece of meat has been exposed to the air for several months, and has as yet undergone no alteration.

Urine to which one forty-thousandth part of aniline violet had been added was placed in a test-tube in contact with the air, and at the end of six months had undergone no putrefaction.—LANJEROIS, *Revue de Thérap.*, No. 9; *The Western Lancet*.

GLEANINGS FROM OUR EXCHANGES.

TRACHOMA TREATED BY GONORRHOEAL INOCULATION.—Dr. Léon Brière reports in the *Bulletin Générale de Thérap.*, September 15, 1873, four hundred and four cases, from various sources, of pannus treated by the inoculation of blennorrhagic virus, derived either from the ophthalmia of the new-born, or from urethral or vaginal blennorrhagia. To these he adds five cases in his own practice. Having quoted with approval the conclusion of Roosbroeck, who has never seen any grave accident follow so seemingly frightful a plan of treatment, and who observes, "I regard these results as so complete, so marvellous, and so extraordinary, that I do not believe anything more beautiful exists in all ophthalmology," the author sums up in the following indications and contra-indications:

1. Inoculation gives results satisfactory in proportion as the pannus has arrived at a very high degree of development (without incurable complication on the ocular surface). 2. In pannus which is generalized over the whole surface of both corneæ, accidents are most rare. 3. Inoculation must never be practised in cases of unilateral pannus, as the most scrupulous care of the sound eye will not save it from contagion. 4. Inoculation is equally contra-indicated where the pannus is partial and where the cornea presents points. 5. In cases of double pannus, it is preferable to inoculate both eyes at the same time. It is a matter of indifference whether the inoculating matter be taken from an ocular, vaginal, or urethral blennorrhagia. An individual refractory to the influence of one kind may be affected by another virus, seemingly less active. The pus of acute urethral blennorrhagia is more active than that of the chronic disease. The material of inoculation should be picked up with a pair of forceps and deposited upon the palpebral conjunctiva. If its escape be feared, the conjunctiva may be punctured with a lancet or needle. The course of purulent ophthalmia of artificial induction is the same as that of accidental origin. Should the cornea not ulcerate, frequent applications of warm water should be made. Van Roosbroeck lets the affection take its own course. Should the cornea exfoliate (intense pain), Warlomont recommends the application of the nitrate of silver, in stick or solution.—*New York Medical Record.*

CONGENITAL STRANGULATED HERNIA IN AN INFANT (*British Medical Journal*, January 3, 1874).—Dr. Robert Somerville reports the case of a healthy boy, aged ten days, who, in the middle of the night, was seized with an attack of vomiting. It was soon after observed that he had a considerable tumor in the scrotum on the right side. There was no fever, and no unnatural fulness in the abdomen, but the vomiting persisted.

On examining the scrotum, it was evident enough that the swelling was an inguinal hernia. The testicle of the right side was felt in contact with the protruding end of the hernia, but the cord could not be made out, being lost in the tumor. On the left side both the testicle and cord were found in good condition. The handling of the hernia caused a good deal of pain to the child, so that taxis was not much persisted in, and was quite unavailing. At the same time, the symptoms did not seem very urgent; and, as the tumor was not so large as when first observed, it was decided to wait, enemata being administered, and carminatives being used to prevent the child's crying. In the evening the tumor was somewhat less than in the afternoon, and the child was easier, though the hernia could not yet be reduced, and there was no action of the bowels. Next morning the hernia was gone. The bowels had acted during the night, and the vomiting had ceased. With the exception of slight feverishness, which passed

off during the course of the day, the child was quite well.

No doubt the hernia was congenital and strangulated. Its rare occurrence at such an early age, and its spontaneous cure, seem to make it worthy of record.

CASE OF OVARIOTOMY (*New York Medical Journal*, February, 1874).—Dr. Charles H. Richmond reports the case of a married woman, 24 years of age, who consulted him concerning the continuance of the catamenia, which were regular, although she supposed herself to be six months advanced in pregnancy. It was found that she had an ovarian cyst. She was tapped once to relieve the abdominal distention, and finally, two years after the first appearance of the tumor, she was operated on in the usual manner, being anesthetized with bichloride of methylene. On reaching the peritoneum, that membrane was found congested and thickened, and it bulged through the wound, indicating the presence of free fluid within its cavity. It was laid open on a director, and a large quantity of serum escaped.

The tumor was found to weigh twenty or twenty-five pounds, and to have extensive pelvic and intestinal adhesions. It was then enucleated, the operation being concluded in thirty-eight minutes. Only one artery was tied, and the oozing which followed was controlled by the free use of persulphate of iron.

Fever, vomiting, and tympanites continued for a few days subsequently, indicating some peritoneal inflammation, the patient being sustained by brandy, iced champagne, and enemata of beef-tea and quinine. After seven or eight days a serous discharge occurred near the pedicle, and about the fifteenth day became purulent and offensive. From the seventeenth to the twenty-fifth day considerable quantities of black, membranous sloughs were discharged through the opening near the pedicle. In a week or two more this discharge ceased, and soon after the patient completely recovered.

A NEW SOLVENT OF PHOSPHORUS (*American Journal of Pharmacy*, January 1, 1874).—Mr. A. W. Gerrard has found that resin—"the residue of the distillation of the turpentine"—is capable of dissolving four or more per cent. of phosphorus. He melts the resin, and, while it remains fluid, adds the phosphorus, a piece at a time, and in the proportion of four of the latter to ninety-six of the former. The bottle, during this process, should be kept in a sand-bath at a temperature between 200° and 210° C. He calls the resulting substance phosphorettered resin, and suggests the following formula for its exhibition:

R Phosphorettered resin (4 per cent.), 25 grains;
Powdered white sugar, 75 grains;
Tincture of Tolu, a sufficient quantity.

Pulverize the resin, mix with the sugar, and form into a mass with tincture of Tolu,—eight to ten drops are sufficient,—then divide into twenty pills; each pill will contain one-twentieth of a grain.

EMPLOYMENT OF METALLIC MERCURY (*The Lancet*, January 10).—Dr. Kirchstein relates a successful case of the above. The patient was a robust fisherman, subject to cramps in the stomach. There was complete obstruction of the intestinal canal, with tympanites, fecal vomiting, etc. All the usual external and internal means proved unavailing. After five days, and when the prognosis became most grave, Dr. Kirchstein thought of metallic mercury, and two tablespoonfuls, at half an hour's interval, were administered in the evening. The vomiting soon ceased, and towards the morning the patient passed a great many hard, charcoal-like scybala. He rapidly recovered. During the three weeks following, evacuation of globules of mercury was observed.

DOUBLE SPLEEN AND KIDNEYS (by Surgeon-Major G. W. Jameson, Civil Surgeon, Ghazee-pore).—The following is an extract from the notes of a post-mortem examination performed on the body of Bickhoo, resident of the city of Ghazee-pore, on the 28th of October, 1873.

In addition to one healthy well-developed spleen, there was a *second* similar one, connected with the abdominal vessels by separate communications of its own, and situated between the ordinary spleen and the liver. The smaller was of a roundish shape, and had a distinct hilus.

Weight of first spleen, 9 oz. 1 dr. 6 gr.

Weight of second spleen, 1 oz. 1 dr. 30 gr.

Besides the above abnormality, there were four kidneys: two of these were well developed, healthy, and in the usual situation, while the second pair were small, intensely inflamed, and situated lower down than the other.

The four kidneys had each their separate arterial and venous attachments and ureters.

Weight of the two normal kidneys, 5 oz. 4 dr.

Weight of the two smaller kidneys, 1 oz. 4 dr. 24 gr.

The bladder was exceedingly small, walls much hypertrophied, and the mucous coat somewhat inflamed.

No calculus in bladder or urethra, and no stricture.

The mucous coats of both large and small intestines were inflamed and ulcerated.

Tissues infiltrated, and abdominal cavity filled with dropsical fluid.

Blood unusually fluid, no coagulum in any part of body; all the other organs tolerably healthy in appearance.—*The Indian Medical Gazette*.

ELECTRICITY IN PARTURITION.—Dr. Ulisse Martemucci (*Lo Sperimentale*) says that already in 1871 he had used electricity as an important assistant in cases of labor with uterine inertia, when ergot or rye had failed.

The method consisted, in one case, in applying the induced current, placing one electrode, with a moist sponge, on the right side of the abdomen, at the level of the umbilicus, and the other, also with a moist sponge, on the left, running over the abdominal muscles, first with the one and then with the other. In fifteen minutes the fetus was expelled, dead, without the use of forceps, which are always dangerous. In the *Gazzetta di Torino*, 1873, he reports two other similar cases, in both of which the children were born in the best condition of health. Also, in eight other cases he succeeded without the use of ergot. He observes that the labor takes place much more rapidly thus than when ergot is used, and that in these eight cases he never lost one fetus; whilst with ergot he lost one in four. Hence he derives the following corollaries. 1. By using electricity, the obstetrician has in hand a method of causing the cessation of uterine contractions whenever he chooses; whilst, when ergot is used, the action is constantly kept up. 2. When ergot is used, it is necessary that the labor should be speedily finished, on account of the feticidal properties of the drug, because the fetus and placenta are so compressed as to make circulation difficult. 3. By the electric current, also, the obstetrician can leave off by turns, and again recommence the uterine contraction, which he cannot do in cases where ergot is used.—*The Doctor*.

CHLORAL IN CHOLERA.—In a report of nineteen cases of cholera treated by the hypodermic injection of chloral, contained in *The Indian Medical Gazette* of January 1, 1874, Dr. F. W. Higginson concludes as follows:

"An analysis of the treated cases shows that 89 per cent. of the entire number recovered; seven of them were in intense or severe collapse; two died; seven

were in mild collapse, all of whom were cured. In the others, collapse was warded off. The hypodermic injection was the sole treatment employed; the patients were supplied with cold boiled water to drink *ad libitum*: they were nearly all exceedingly poor, living in wretched huts. During their convalescence, the only nourishment they could afford was a very limited quantity of milk. The immediate beneficial effects of the remedy cannot be better described than by the expression so often used by my patients, 'I feel more life in me.' No ulceration whatsoever occurred where the injection had been made, a slight sensation of pain and hardness being all that resulted."

ECTROPION VESICÆ WITH EPISPADIAS (*The Lancet*, February 7, 1874).—At a meeting of the Royal Medical and Chirurgical Society, Mr. John Wood showed two cases which had been operated on with success by his plastic method. Two plastic operations had been performed on each. The first consisted of a reversed flap of skin taken from the umbilical region, large enough to cover the exposed bladder, and turned down with its skin-surface towards the mucous membrane. The skin of the flap was in this situation quite devoid of hair, as is usual in these cases. Two other flaps of a lancet-shape were then taken, one from each groin, with the bases downwards, and placed upon the raw surface of the reversed flap. They were held together by harelip-pins and wire sutures. The second operation was effected by the transplantation of the anterior three-fourths of the scrotum from below the malformed penis to its upper surface, covering in the urethral epispadiac groove and forming a very complete prepuce, through and under which the urine flows, and completely enveloping the glans penis above and at the sides.

The result was highly satisfactory in both cases, and the patients were about to have a shield made with an india-rubber urinal attached, to fix on the restored penis and fasten to the leg, and thus enable them to keep dry and comfortable.

HEPATIC EMBOLUS (*The Lancet*, February 7, 1874).—Mr. L. W. Marshall reports the case of a laborer, æt. 21, who was crushed between two wagons. When he came under observation he was suffering severely from shock, and death ensued forty minutes after the occurrence of the accident. On the post-mortem examination the right clavicle and all the ribs on both sides, at their junction with the costal cartilages, were found to be fractured, the sternum, however, being uninjured. The peritoneal cavity was filled with blood, and on throwing back the abdominal parietes a long rupture was seen to pass nearly through the substance of the liver at the junction of the two lobes. The diaphragm was also torn at the upper part. On examining the heart, the right cavities were found to contain some clots, the left being empty and contracted. There was no valvular mischief. In the pulmonary artery, lying immediately in front of the valves, and almost filling the arterial tube, was found a piece of liver, conical in shape, and weighing a drachm.

The fact of a patient living for forty minutes after the receipt of such an extensive injury is remarkable; but that he should have lived so long with a piece of liver, which must have passed through the right side of the heart, fixed in the pulmonary artery, is truly surprising.

CASE OF LUMBAR HERNIA (*New York Medical Journal*, February, 1874).—Dr. W. N. Campbell reports the case of a boy, æt. 4 years, who, eighteen months previously, had suffered from an abscess in the left loin between the crest of the ilium and the last rib. It had been lanced and poulticed, and had continued to discharge until about a month before he came under ob-

servation. Then another tumor made its appearance at the point where the quadratus lumborum and latissimus dorsi intersect the external and internal oblique muscles. It became the size of a goose-egg, was soft and fluctuating to the touch, resonant on percussion, and could be reduced by performing taxis forward and inward, reappearing upon the patient's coughing or making muscular exertion. It was diagnosed to be a lumbar hernia, due, probably, to a disintegration of the muscular fibres of these muscles, owing to the long-continued discharge from the abscess.

LIGATURE OF THE CAROTIDS (*Detroit Review*, February, 1874).—Dr. Longworth draws the following conclusions respecting the therapeutic value of the several operations on the carotids:

1. Ligature of the common carotid is the widest in its application, but most dangerous and least efficient.
2. Ligature of the external carotid, below the digastric and stylo-hyoid muscles, is more limited in its application, but less dangerous and more efficient.
3. Ligature of the external carotid, above the digastric and stylo-hyoid muscles, is the most restricted in application, but also safest and most effectual.
4. Ligature of the external carotid on both sides has hitherto been uniformly successful, and is the most efficient measure at our command for arresting the distal circulation.

A KNIFE SWALLOWED, AND PASSED THROUGH THE ABDOMINAL WALL AFTER AN INTERVAL OF NINE WEEKS.—A female, 26 years old, during an attack of delirium tremens, swallowed a dessert-knife, the metal part of which measured six inches and a half. Eight weeks later a globular swelling made its appearance in the right side, nearly on a level with the umbilicus, and the sharp edge of a foreign body could be felt distending the skin, which was freely movable over the tumor. After some days the blade of the knife protruded through the skin, and was easily removed by slight traction without additional incision. The ivory handle had been entirely digested, and the extremity of the blade was rendered very thin by the action of the gastric juice. The nervous shock was considerable at the time of the removal of the offending body, but a good recovery was made without the formation of a gastric fistula.—*Liverpool and Manchester Medical and Surgical Reports*, 1873; *The Clinic*.

TETANUS NEONATORUM (*Boston Medical and Surgical Journal*, February 12, 1874).—Dr. Hüttenbrenner has drawn the following conclusions as the result of recent clinical experience:

1. Tetanus is not an absolutely fatal disease.
2. It can run through its course with or without fever. Those cases running a rapid course with high fever are the result of a general poisoning of the blood, whilst those cases without fever are to be regarded as of reflex origin and due to some peripheral irritation.
3. The cases without fever have a more favorable prognosis, although where the fever is high the prognosis is not absolutely a fatal one.
4. Chloral hydrate is by no means a specific, but is a remedy preferable to all others: (a) because it is a pure hypnotic; (b) because it has no unpleasant after-effects, as morphia has, causing hyperæmia of the brain; (c) because it is easily administered, and a cumulative action is very rare.

TEMPERATURE IN CASES OF INJURY OF THE SPINAL MARROW (*Irish Hospital Gazette*, February 2, 1874).—In consequence of numerous pathological observations and physiological experiments, Dr. A. H. Corley has arrived at the following conclusions: 1. There is a heat-regulating region of the cord, extending probably from the third cervical to the upper dorsal vertebræ.

2. This function resides in the gray matter. 3. The effects of injury differ, a simple lesion giving negative results, while a continual irritation produces thermal symptoms. 4. Nearly all the phenomena of ordinary fevers may be explained by an irritation, such, for example, as a blood-poison, acting in this particular region.

GALVANO-EMESIS.—Emesis may be produced by means of electricity, when other means fail or are impracticable. It may be brought about by introducing an electrode into the upper part of the œsophagus, and applying the other over the epigastric region. Dr. Fox relates a case, in the *British Medical Journal*, in which a child was brought to him in an asphyxiated state from eating poisonous mushrooms. He applied the current as above prescribed, and vomiting ensued immediately.—*Western Lancet*.

TRAUMATIC TETANUS.—**CALABAR BEAN.**—**DEATH.**—Dr. Charles B. Brigham reports (*Western Lancet*, February, 1874) a case of tetanus following wounds of the scalp and finger, in which death occurred in spite of the use of spinal ice-bags, chloroform, Calabar bean, and the continued galvanic current.

MISCELLANY.

A NATIONAL BOARD OF HEALTH.—The Congressional House Committee on Commerce, on January 28, authorized the chairman to report the bill to prevent the importation of contagious or infectious diseases into the United States.

It provides that the surgeon-generals of the army and navy, and the supervising surgeon of marine hospitals, of the Treasury, shall constitute a board of health, with the power to establish and enforce such rules and regulations as are necessary to prevent the importation of contagious diseases; and the regulations, when approved by the President, shall have the force of law. It does not allow any interference with State or municipal regulations.—*Medical and Surgical Reporter*.

THE Lepus Bairdii is a peculiar species of rabbit which is found in the mountains near the Three Tetons of Wyoming and the heads of the Snake River and the Missouri. One of its peculiarities is the habit which the males have of suckling the young. Numerous specimens of this sex were obtained by the naturalists of Hayden's geological survey of 1872, with well-developed teats and mammary glands filled with milk.

GUM camphor and hydrate of chloral, when mixed together in equal proportions, are converted, in the course of a few days, into a clear, colorless liquid.

NOTES AND QUERIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next meeting will be held Wednesday, March 11, 1874, at 8 o'clock P.M.

The subject before the meeting will be "The Philadelphia County Medical Society."

The paper will be read by Dr. L. J. Deal.

All regular practitioners of medicine are invited.

SATURDAY, MARCH 14, 1874.

ORIGINAL COMMUNICATIONS.

ON THE LOCAL TREATMENT OF PULMONARY CAVITIES BY INJECTIONS THROUGH THE CHEST-WALL.

BY WILLIAM PEPPER, M.D.,

Professor of Clinical Medicine in the Hospital of the University of Pennsylvania.

FOR some weeks past I have been experimenting with a mode of treating pulmonary vomicae, which, so far as I know, has not hitherto been employed, and which has yielded results that, although as yet very imperfect and crude, seem to me to have an important significance. During the last year and a half, reiterated failures in the treatment of pulmonary phthisis in the stage of softening, with formation of cavities, either by general medicinal agents, by inhalations, or by change of climate, have led me to think constantly of the possibility of bringing powerful remedies into immediate contact with the diseased tissues by injecting them through the chest-wall. Circumstances have prevented me from putting the resolution I had formed into effect until recently; but the attempts I have made show so conclusively the simplicity and harmlessness of the treatment adopted as to induce me to publish a brief account of them. It is evident that the therapeutic value of this local treatment can be determined only by repeated and prolonged trials.

Case I.—W. S., æt. 29 years, by occupation a metal-polisher, has been in my ward in the Philadelphia Hospital for some months. His father worked in the same factory, and died of phthisis, as did his mother and one of his brothers. At the age of eleven years he was confined to bed for eleven months with coxalgia, which left him lame. Since then he has enjoyed general good health until August, 1872, when cough began, and was soon accompanied with muco-purulent sputa. In October, 1873, he had a slight attack of hæmoptysis. After this his general health, which had not been much affected before, began to fail rapidly; he lost flesh and strength, had marked hectic, and greatly-increased dyspnœa. There was much pain over the right apex, troublesome cough, and abundant purulent expectoration. There was no recurrence of hæmoptysis, but his condition remained about the same, with occasional fluctuations, until the early part of the present year, when he suffered severely with increased cough and hectic. On February 17, 1874, his condition was found to be as follows. He is much emaciated, and is very easily fatigued. There are no marked digestive symptoms. His breathing is very short, and this is much increased by exertion, so that it is difficult for him to ascend a single flight of stairs. His cough is painful, exciting pain especially on the right side of the chest, but is not very severe at present, and is attended with but a moderate amount of purulent expectoration. The frequency of the pulse is somewhat variable: at present it is 108.

Upon physical examination, the chest is found to be chicken-breasted. The physical signs on the left side are normal, save some roughness of the respiratory murmur, and a few crackling sounds at the apex.

On the right side there is tympanitic resonance, even on light percussion, from the clavicle down to

the fifth rib; the most marked (amphoric) tympany is heard at the middle of the second interspace. There is cracked-pot sound for two and a half inches to the right of the sternum from the second to the fifth rib. Auscultation reveals blowing breathing on inspiration and expiration over this whole area,—the character of the blowing, however, varying at different points. Over the seat of cracked-pot sound it is very superficial and is rather shrill and high-pitched, and accompanied with large, moist, and gurgling râles. Outside of the line of the nipple it is larger, lower-pitched, and free from râles. There is intense pectoriloquy over this entire area.

His treatment has been very varied, but without any permanent relief, and the course of the case has been gradually downwards. On February 20, the No. 1 needle of Dieulafoy's aspirator, with the syringe attached, was introduced to the depth of about one inch in the second interspace on a line with the right nipple. He complained merely of a slight sensation of tingling and numbness, extending down the right arm. There was no cough excited, and not a drop of blood followed the puncture.

February 24.—The same needle was introduced at the point of the original puncture to the depth of one and seven-eighths inches, and was followed by the escape into the vacuum of a few drops of offensive watery pus. The needle was very tightly bound by the tissues through which it passed, but some motion could be imparted to its end, indicating that it was in a free space. Three or four minims of a mixture composed of liq. iodinii comp. gtt. ij to f3i of tepid water were then injected through the canula by a hypodermic syringe.

The operation was followed by loose, rattling cough, and the expectoration of about three fluidrachms of fresh, frothy blood. He was immediately put to bed, and the cough and hemorrhage soon stopped. His temperature in the evening and the following morning was only 99° F.

February 28.—The cough has been about as before; yesterday a trace of blood was mixed with the sputa. To-day the breathing-sounds over the right apex are very dry, scarcely any râles being heard. There is no external irritation around the seat of puncture. The same needle was again introduced to the depth of one and seven-eighths inches at the same point, and six minims of iodine-solution, of double the former strength, were injected. There was tingling pain down the right arm while the needle was in place, but no other symptoms attended or followed the operation.

March 5.—Since the last puncture, he has been feeling very comfortable. There has been no hectic; the cough is less severe, the sputa more scanty and whitish. He is bright and cheerful, and states that his dyspnœa is greatly relieved. The same needle was introduced to the same depth at a point one-eighth of an inch nearer to the sternum. The puncture was immediately followed by a rapid flow of fresh, frothy blood into the vacuum, about one and a half fluidrachms escaping. The pump was detached, and ten minims of iodine-solution were injected. He was put to bed immediately, but scarcely any cough, and no hæmoptysis, followed.

March 8.—The patient is brighter and more cheerful than for months past. There is no hectic irritation, the temperature never rising above 99° or 99.5°. The pulse ranges about 84. His breathing is so much relieved that he has walked up three long flights of stairs without much dyspnœa. The cough is but little troublesome, and only a few white, frothy sputa are raised. Auscultation shows that many of the râles formerly heard over the right apex have disappeared. There has also been some increase in flesh. All internal medication has been discontinued.

Case II.—John Wilson, æt. 35 years, born in Finland,

was admitted to my ward in the Philadelphia Hospital February 7, 1874. His family is subject to phthisis. He has been a seaman, and had enjoyed general good health until three years ago, when a short, dry cough began, with pain about the left apex. Muco-purulent expectoration soon commenced, followed by dyspnoea, hectic fever, night-sweats, and emaciation. Hæmoptysis first occurred in June, 1873, and since then he has several times raised small amounts of blood. For the past three months there has been much acute pain over the left apex, and his other symptoms have been aggravated. He is now much emaciated, and incapable of exertion.

Physical examination of the right side reveals nothing abnormal, excepting exaggerated respiratory murmur over the whole lung, with slightly prolonged expiration at the apex, and marked percussion-resonance. On the left side the respiratory movements are impaired. There is depression of the infra-clavicular region. Below the clavicle there is dullness on percussion down to the lower edge of the first rib; below this, down to the fourth rib, there is tympanitic resonance, with cracked-pot sound on strong percussion. There is also dullness over the apex posteriorly down to the spine of the scapula. Over the lower portions of the lung resonance is somewhat impaired as compared with the right side. There is loud amphoric breathing heard over the left apex as far down as the fourth rib; most marked in the second intercostal space above the nipple. There are also large and small bubbling râles over the rest of the lung anteriorly and laterally, with some weakness of the respiratory murmur. Posteriorly, above the spine of the scapula, loud bubbling râles are heard; and below, fine mucous râles.

There is increased vocal fremitus and distinct pectoriloquy over the left apex.

The No. 1 aspirator-needle was introduced about one and three-fourths inches in depth in the second intercostal space, about one inch outside of the line of the left nipple. There were the distinct signs of a cavity at this point, and the freedom with which the end of the needle could be moved about showed that it had entered a free space. A few drops of sanious fluid entered the vacuum; and seven minims of dilute Lugol's solution were injected. The operation did not cause cough or hæmoptysis, and was followed by no pain, acceleration of pulse, or elevation of temperature.

Case III.—James Hill, æt. 27, was admitted to my ward in the Philadelphia Hospital. His father died of phthisis; he himself enjoyed good health until November, 1871, when cough set in after an attack of rheumatism. It was at first dry, but later has been accompanied with purulent sputa. He first spat blood in July, 1872, and since then he has had quite frequent small hemorrhages. He has suffered much from pain in various parts of the right lung. He has had comparatively little hectic fever, but has lost much flesh and strength.

Physical examination shows contraction and comparative immobility of the right side; enlargement of the left side, with slight curvature of the dorsal spine, and deviation of the sternum. The left lung is hypertrophous and healthy. There are the physical signs of a quite large cavity at the right apex, with marked thickening of the pleura and partial induration of the lung below. The heart pulsates to the right of the sternum.

At a spot in the second intercostal space, half an inch outside of the line of the right nipple, there is deep-seated tympanitic resonance, which on strong percussion is amphoric with slight cracked-pot sound; cavernous breathing, both in inspiration and expiration, with bubbling râles with amphoric echo, and marked pectoriloquy for the spoken and whispered voice. The No. 1 aspirator-needle was introduced here to the depth of one and seven-eighths inches, and evidently entered a cavity. About seven minims of dilute Lugol's solu-

tion were injected. The operation produced a paroxysm of spasmodic cough, but was followed by no hæmoptysis or irritation.

The only point which can be said to be demonstrated by the above cases is the possibility of puncturing superficial pulmonary cavities and injecting into them small quantities of dilute solution of iodine. And when it is seen how simple is the operation, it can only be wondered at that it has not long since been attempted, and its value determined. In estimating its danger, it is to be borne in mind that in the majority of cases when this treatment, if found of real curative value, will be called for, there exist pleuritic adhesions which will prevent the development of pneumothorax, even if so minute a puncture of the pulmonary pleura as is needed would allow the escape of any noteworthy amount of air.

Again, in treating the lung-tissue in this way, we are quite free from any fear of ill consequences from admitting air to the cavity, since, of course, it is already filled with it. The puncture would generally be made at a point of the lung where there are no large vessels or bronchi, and in conditions of the lung-tissue where many of the blood-vessels are obliterated. In case of an injury to a very small vessel, further, it does not seem likely that any uncontrollable hemorrhage would ensue. Still, it is evident that the danger of hemorrhage, as well as the ability to control it by injections of astringents through the canula, are questions requiring further observations to settle. My own limited experience, and the general considerations I have suggested, lead me to regard the danger of serious hemorrhage as but slight, if the puncture be carefully performed.

If it be established that the operation may be performed with safety, it remains to be considered to what classes of cases it is most suitable; in what manner it may best be performed; what local applications can advantageously be employed by this novel method; and what curative results can be obtained by it. It is evident that it finds its most simple application in the treatment of superficial pulmonary cavities. We have here an ulcerated surface separated from the skin merely by the intercostal tissues, thickened pleura, and a layer of infiltrated and indurated lung-tissue. It is difficult to imagine any serious consequences which can follow the puncture of such a cavity with a delicate needle. In such cases of phthisis with vomica, moreover, all means of treatment hitherto adopted are proverbially ineffectual. To how great an extent this is dependent upon the constitutional nature of many forms of phthisis is well known. But, in the light of our more correct knowledge of the local origin of some cases of phthisis, it is probable that their incurable character depends in a great measure upon our inability to maintain the affected part at rest, and to bring in contact with the diseased surface suitable agents of sufficient strength to modify the morbid action. It is probable, therefore, that this mode of treatment will find one of its most successful fields of application in chronic non-tuberculous cavities in the lungs, in cases where the remaining lung-tissue has not become the seat of secondary tuberculous

formations. It is of course uncertain how much curative action we may be able to exert in such cases by any local application made through a canula. In the only case I have reported where the treatment has been continued long enough to produce any decided action, it is unquestionable that a certain degree of positive improvement has occurred both in general symptoms and local signs. And I am encouraged to hope that, with further experience, definite modes of treatment may be formulated which will prove of material benefit in this hopeless class of cases.

Further, I cannot see why, if it be not injurious to pass a delicate needle through the infiltrated wall of a cavity, we may not introduce it into the centre of superficial circumscribed indurations or caseous infiltrations of the lung-tissue, and make such injections as may tend to induce absorption or reparative action. Finally, it appears to me that we have in this mode of making local applications to the lung-tissue, a valuable means of treating some cases of severe hæmoptysis, especially when the hemorrhage proceeds from a well-defined seat of disease.

In regard to the mode of making the puncture, I have hitherto employed the finest (No. 1) of the needles accompanying Dieulafoy's aspirator, and have used it with the "previous vacuum" attached. For the first exploratory diagnostic puncture it is probably desirable to employ an aspirator, as it would also be if it were desired to empty such cavities before injecting them. But for the continuance of the treatment it will perhaps be quite as well to use a capillary canula, with trochar which can be withdrawn, so that a syringe can be fitted to the canula and the injection made. I have employed local anæsthesia by freezing, and have directed the patients to take a full breath and to hold it before the puncture was made. It will, however, be understood that my procedure is in all respects purely a tentative one thus far, and that, if this mode of treatment prove of value and worthy of pursuance, many improvements will undoubtedly be made.

The only fluid which I have as yet injected has been dilute Lugol's solution ($\mathfrak{M}\text{iv}$ to $\mathfrak{f}\mathfrak{3}\text{i}$), of which from four to ten minims have been injected. The entire absence of signs of irritation makes me confident that a larger quantity could be introduced without injury. This substance appeared suitable for the cases in which I have thus far operated. It is probable that other solutions, astringent or antiseptic, may be found preferable in some cases. In cases of local consolidations, solutions of iodine might also be expected to prove most beneficial.

I design employing a dilute solution of Monsel's salt for injection in suitable cases of serious hæmoptysis.

The practical value of this mode of treating pulmonary diseases is as yet uncertain. But it has appeared to me that, considering the almost hopeless nature of some of these lesions, the proof that a puncture may be made into the lung-tissue and remedial agents brought into direct contact with the seat of disease without any serious danger calls for a patient trial of it.

NOTE.—Since writing the above for publication,

I observed on Saturday, March 7, in both the *Medical Times and Gazette* for February 14, 1874, and in the *Medical and Surgical Reporter* for March 7, 1874, which reached me on that day, a reference to a paper published by Prof. Mosler, of Greifswald, in the *Berliner Klinische Wochenschrift*, upon the "Local Treatment of Cavities in the Lungs" by injecting certain drugs through the wall of the chest into superficial caverns, and leaving the canula in, so as to repeat the operation frequently at discretion. These two brief references are the only notices of Prof. Mosler's paper which have reached me; and, as no opportunity is afforded me for consulting the original at present, I am unable to say how far my independent observations may agree in results with his.

PHILADELPHIA, 1811 SPRUCE STREET,
March 9, 1874.

A CASE OF FIBROID TUMOR OF THE UTERUS WITH INTERESTING CLINICAL HISTORY—DEATH FROM PELVIC ABSCESS.

BY JAMES TYSON, M.D.,

One of the Visiting Physicians and Pathologist to the Philadelphia Hospital.

MISS R. B. W., æt. 36, had been under my observation socially, and, at intervals, professionally for trifling ailments, during more than ten years. Though she was somewhat nervous, and subject to violent sick-headaches, I can recall nothing bearing upon her last illness prior to July, 1873. On the 1st day of April, however, she sent for me, when I found her in a state of great nervous excitement, having just returned from a visit to a neighboring city, where she had been ill for several days, apparently from the effects of cold contracted during unusual exposure in travelling. The weather had been very severe, and she had been compelled to wait at night, in an exposed situation, the arrival of a train. The most prominent symptoms of this attack were a chill and very severe pain in the back, attended with some fever. She was appropriately treated; but there happened to be an epidemic of cerebro-spinal meningitis pervading the town in which she was staying, and while there she lost an intimate friend from this disease. The impression on her was a very powerful one, and she evidently conceived the idea that she might be suffering with this affection,—an apprehension which was encouraged by the remarks of friends who suggested that her symptoms were very like those of the disease in question. As soon as she was able, she came home, in the state of alarm referred to, and sent for me. After careful examination, finding no foundation for her apprehensions, I reassured her, saw her on each of two succeeding days only, and then discharged her in good spirits and apparent health. These are the well-known phenomena of an influenza; and yet I have thought best to record them, on account of the pain in the back and the exalted nervous symptoms then manifested, though I think it will appear that there was evidently no necessary relation between this illness and that of which she died.

A few days later she paid a visit to New York, where she remained more than a month, going about a good deal, and much enjoying her visit. On the 13th of July I happened to be calling socially at her home, when her sister informed me that Miss W. had not been well for several days, and asked me to see her. I learned that she was suffering with nausea and some

derangement of menstruation,—i.e., she had commenced to menstruate as usual, but the flow had ceased, reappeared slightly, and again ceased. She had always menstruated scantily, but had not suffered peculiarly at such times. She attributed this derangement to unusual exertion in walking on a very hot day. I recommended the repeated use of hot foot-baths, quinia, and a little blue mass at bedtime. It was evening, and my attention was not particularly attracted to her appearance. Two days later, on the 15th of July, she sent for me. I was then impressed with her appearance. She was pallid, wan, and had evidently been running down. For this there seemed abundant reason. I was informed by those who had been about her that, despite all warnings and entreaties, she had insisted upon confining herself closely to the house, sewing late at night, during the hot weather of June and early July. This she was, however, unwilling to admit. I found upon inquiry that menstruation had reappeared scantily, but had disappeared, notwithstanding the use of the hot baths. As she had no other symptoms pointing to uterine disease, and as the period for attempting to restore the menses seemed past, I directed my attention to her general condition, continuing the restorative treatment and remedies for the bowels, which acted imperfectly, apparently accounting for the persistent nausea and imperfect digestion. She appeared to improve, and by Sunday the 20th was much better,—indeed, thought herself almost well. I continued to visit her on alternate days until Friday, when I paid my last visit. She shortly afterwards left Philadelphia to spend some weeks with relatives residing on the Hudson River above New York City, where I saw her on the 29th of August, looking much better, and apparently in good spirits. Under the anxious care of her relatives, who sought by every conceivable device to build her up and amuse her, she gained flesh and strength, while at the same time she impressed those constantly about her that she was ill at ease or had something preying on her mind. This was at the time unknown to me, and I left her (the visit was purely a social one), believing that she was rapidly recovering. At this time, also, I questioned her with regard to menstruation, and learned that, although her last period was not strictly normal, yet it was more natural, and she evinced no concern about it. On the 18th of September she sent for me, having returned to Philadelphia on the 12th, and, for the first time during her illness, I found her in bed. She was greatly excited,—in a condition similar to that in which she was after the attack of influenza on April 1. She sought to be cheerful, however, and confessed that for some time she had been under the impression that “she had a tumor,” which she located in the right groin,—that it did not maintain a uniform size, but was sometimes as large as her fist. I at once examined her abdomen, and found absolutely no evidence of the presence of a tumor. There was no swelling in the groin, and the belly was normally tympanitic throughout. She had just finished menstruating, and said that the period was the most natural one she had had for years, though the flow was more than usually copious. She had had a daily chill for two or three days previous, but, as she had been spending the summer in a malarious district, this was amply accounted for. There was no febrile movement, and the pulse, though not full, did not seem particularly feeble for a frame so slight as that of my patient. I prescribed a sedative mixture, arranged for the administration of quinia in antiperiodic doses, and left her.

On the following day she was apparently better, though in bed, with a book at her side, which she had been reading. In the evening, however, she sent for me, when she appeared very nervous, restless, and complained of pain, which, starting in the right iliac region,

seemed to follow the course of the large intestine. I again examined the abdomen, found it slightly more tympanitic, but there was *no tenderness*, and the pain was ascribed to flatulence. A hypodermic injection of one-sixth of a grain of sulphate of morphia gave her prompt relief.

The following day I found her in the same restless and excited condition, and complaining of pain, which, however, she could not precisely locate. It seemed higher up, and more in the back than in the iliac region. Nausea was now added to her symptoms, and it was almost impossible for her to retain any food or medicine. In the afternoon she had several evacuations from her bowels in rapid succession, the last of which alone was loose. The use of bismuth, morphia, and pepsin in powder during the day diminished the nausea and allayed the pain; and, after giving a hypodermic injection, I left her about 10 P.M. in comparative comfort, though towards morning she again had some pain. She was free from it again when I visited her at 9 A.M. Sunday, very comfortable at noon, and at 9 P.M. declared to myself that she was almost well. She had taken continuously of nourishment at intervals throughout the day. I, however, gave her the hypodermic injection at this time to secure a good night's rest. She had a single loose movement of her bowels in the morning of this day. The pulse was not above 90, and her abdomen, to use her own expression, was as flat as her hand. The next morning I was sent for before breakfast. She had been suffering pain since 2 A.M., when, after taking a drink of cold milk and lime-water, the pain suddenly set in, as she described it, when the drink reached the great bowel and began to traverse it. Her belly was now somewhat tumid, and it seemed desirable that her bowels should be opened. Accordingly, I gave her hourly a grain of calomel, at first combined with opium to subdue the pain, but later alone. By midnight twelve grains had been administered without effect. Her restlessness was now extreme, while the difficulty of appreciating her exact condition can be conceived from the fact that, although complaining greatly of pain, she would appear to be relieved whenever I remained in the room, and a hypodermic injection of simple water gave her as prompt relief for the time being as one of solution of morphia. On Tuesday morning I left her for a time, but before returning was sent for, to find her in a state of great prostration. Her pulse the day before did not exceed 100; it was now 120, and feeble. She soon reacted, but the tympany was now considerable, and the indications for a movement of her bowels seemed urgent. Accordingly, an enema of soap and water, castor-oil, and turpentine, to the extent of a quart, was administered, but was retained. Between twelve and one of this day she again became suddenly and alarmingly feeble; the extremities were cold, and the pulse almost gone; and it was only after an hour's continued exertion in rubbing, the use of mustard cataplasms, and large quantities of pure brandy and whisky, that she again reacted. During the afternoon—after 4 P.M.—and the evening the enema was passed, containing, however, little fecal matter, and with no relief to the tympany.

After midnight she again fell into a condition of prostration, from which it seemed impossible for her to rally; and the administration of nourishment and remedies was discontinued, in the belief that she was dying. Notwithstanding this, she again rallied towards morning, and stimulants and nourishment were again plied. Thus she sank and rallied throughout the day, reacting less completely after each sinking-spell, until at 5 P.M. she was in a state of complete collapse, her extremities cold and clammy, pulse 150,—scarcely perceptible,—but her mind was perfectly clear, and she expressed herself as “better, much better.” She died, finally, at

5 A.M. of the 25th of September, answering all questions intelligently up to within an hour of her death.

A post-mortem examination was made about twelve hours after death. The intestines were much distended with gas, which escaped rapidly on puncture. Superficial examination of the abdominal contents after laying back the abdominal walls revealed nothing; but on drawing up the intestine from the right iliac region, where seventy-two hours previously we had located the lesion, whatever its nature, there was seen to well up from the pelvis a mixture of pus and blood in considerable quantity,—at least an ounce. The collection was surrounded by the usual products of a circumscribed peritonitis, to a considerable degree organized: indeed, the abscess, for such it really was, may be said to have been encysted. In seeking for the cause of this extraordinary condition, the pelvis was further explored, when, lying in the hollow of the sacrum, firmly adherent to the viscera just below the promontory, was found what was at first thought to be the body of the uterus, but which on further examination proved to be a succulent tumor, nearly spherical, and about three and a half inches in diameter. This was attached by a broad pedicle to the right half of the body and cornu of the uterus. This organ was wider than in health,—perhaps three and one-half inches from cornu to cornu,—but not any longer, and presented no peculiarities about the os. The cavity of the uterus contained two or three very small fragments of a coagulum, traces of the last menstruation. The tumor was encapsulated, and by microscopic examination found to be made up almost purely of fibre-cells, presenting mainly the characters of the unstriped muscular fibre-cell, though some were much elongated and presented the delicate attenuation of the spindle-cells in a sarcoma. There was also a small amount of fibrillar connective tissue. The characters of the tumor were, therefore, those of a *myoma*, while the body of the uterus was enlarged through a hypertrophy of the same element.

With these facts of the examination before us, the *rationale* of the result seems necessarily as follows. The growth having existed for an unknown length of time, causing, perhaps, the frequent pain in the back, of which the patient, as was afterwards learned, was in the habit of relieving herself with dry cups, finally began to suppurate at its posterior adherent portion,—the anterior and lateral parts were quite smooth and uninflamed,—and finally the abscess ruptured into the peritoneal cavity, giving rise to the symptoms of sudden prostration which appeared on Tuesday morning, and the peritonitis which began to show itself in the tympany on Monday. Indeed, the aspect of the abdomen was so like that of a case of general peritonitis that Prof. Da Costa—the privilege of whose counsel I enjoyed during the last two days of her life—remarked that “we would suppose she had peritonitis if its signs were not wholly wanting.” There was, indeed, at no time pain on moving the limbs, which were generally kept in the extended position; nor pain on coughing, nor decided tenderness.

The interesting questions in connection with the case are these: 1. Had this actual tumor anything to do with the imaginary one which the patient thought she had in the right groin? 2. Could the condition have been diagnosed before death?

I think the first question may be answered only in the negative. For, while the patient thought the tumor was in the groin, it lay in the pelvis in the

median line, and *adherent* to the textures in the vicinity of the promontory of the sacrum and below it, so that it could not possibly have fallen over into the region of the right groin, unless, indeed, the adhesion was formed during the last few days, and before my attention was called to the abdomen on account of the suspicions entertained by the patient. Moreover, she had lost a friend nearly four years previously, after operation for a large ovarian tumor, and since that time she had often semi-seriously suggested that she herself had a tumor of a similar nature, though the impression which so greatly affected her was of but two or three months' duration. This impression was so strong that she actually thought her condition was visible in her appearance, and dressed so as to conceal it. And yet, when I first examined her abdomen, one week before she died, it was literally as flat as her hand, and exhibited only normal percussion-sounds.

The second question as to diagnosis may, perhaps, be conscientiously answered as follows: By internal vaginal examination, combined with external abdominal palpation during etherization, the existence of a tumor at the top of the uterus might have been determined. But, apart from the fact that such manipulation, by tearing the delicate adhesions of the succulent mass, might have precipitated the final cause of death,—the entrance of pus into the abdominal cavity,—it is not likely that, with the very slight symptoms of uterine difficulty in an exceedingly modest, unmarried woman of her age, any physician would have thought of suggesting such an examination. That percussion should have given no evidence of its presence is not surprising when we recall the situation and small size of the tumor and the fact that it was first mistaken for the uterus itself.

PHILADELPHIA.

TWO CASES OF APHASIA WITH HEMIPLEGIA.

BY C. SEYMOUR, M.D.,

Northampton, Mass.

THE phenomena attendant upon cases of aphasia, either with or without paralysis, are so interesting to the observant practitioner that I subjoin the following cases from my own experience.

Case I.—Miss Lydia U., æt. 50, twenty years ago had acute articular rheumatism, which undoubtedly implicated the heart, as she had extensive cardiac hypertrophy, and a distinct mitral regurgitant murmur.

On the morning of January 1, 1868, while in the act of dressing,—having a moment previously engaged in conversation with a companion,—she suddenly felt her right arm grow numb and become helpless. After rubbing it awhile, sensibility returned; it regained its strength, and she finished dressing, her room-mate having gone downstairs. When Miss U. entered the breakfast-room she attempted to say “good-morning,” and then for the first time found herself unable to speak. Wishing her sister summoned, she procured writing-materials, but found the only word she could write was “how,” knowing perfectly that it in no way conveyed her meaning. She remained in this state for several hours, but before evening could say one or two words, and the next day could

talk nearly as well as ever. Some weeks after this, on first attempting to write a letter she found herself unable to spell the simplest words, although she had had a liberal education, being a graduate of Mt. Holyoke Seminary. Eventually she regained this faculty, as well as speech. There evidently remained slight paralysis of the right arm, and it was at times the seat of wandering pains.

On November 11 of the same year, after a hearty dinner, she suddenly fell down in a fit of apoplexy, vomited profusely, and was deeply comatose for a time. On returning to consciousness it was found that she was completely hemiplegic on the right side, and had again lost her speech. Slowly but gradually the paralysis improved, more especially in the leg,—the arm always remaining much the weaker limb; but she never again regained her speech. The countenance had none of the apathetic expression characteristic of grave cerebral disease, but was bright and intelligent: her vocabulary, however, had vanished. She could say "yes," "no," and "came," and usually repeated them all in answer to questions. She would instantly apprehend the mistake she had made, and appear annoyed thereat, but would remain silent, as if to intimate her helplessness. The few words she had at command were as distinctly enunciated as ever, showing that there was no paralysis of the articulating apparatus. When asked to write her name she would get as far as Ly, and then always stop, being never able to finish it: this was all she could write; yet she could copy words without difficulty. She could not read, and, what was singular, the only words she seemed to recognize were those pertaining to the Deity. These she would pick out, and signify by gestures her intelligent apprehension of; but words of two or three letters she would point to and shake her head, signifying she did not understand them. She died October 3, 1870, evidently from the cardiac disease; dyspnœa and hæmoptysis being distressing symptoms during the last weeks of her life.

Post-mortem examination of the heart only was held. The organ was greatly hypertrophied, and the mitral curtains loaded with calcareous deposit to the thickness of half an inch by measurement. The orifice consisted of a narrow, irregular slit or button-hole, of course permanently open. This condition of the heart must have been present to a large extent years before the patient suffered her first apoplectic seizure, which might have been from embolism or from clot, but the profound loss of consciousness and permanent paralysis following the second attack probably show that it was the result of hemorrhage in considerable quantity.

Case II.—Wallace P., æt. 4 years. From birth this child had been noted for unusual cranial development, his head being now twenty-two inches in circumference, yet with no indications of its being hydrocephalic. He had been liable to convulsions since infancy, especially at the approach of any febrile disease. Attacks of simple acute bronchitis several times induced them. During the month of October, 1872, he was again attacked with bronchitis, when convulsions suddenly supervened, of a more startling form than ever before: in fact, he may be said to have suffered from a most violent attack of eclampsia for twenty-four hours. He would hardly be released from one fit ere he was seized with another. Every one about him learned to recognize the approach of a convulsion by the premonitory scream, after which tonic and clonic spasms would ensue, lasting for forty or sixty seconds, to be followed by stupor and exhaustion. When at last these convulsions were conquered by bromide of potassium, the child was so prostrated as to be almost comatose for a day and a night. When he did wake up, he was found to be paralyzed on the right side, and speechless. Every effort was made to induce him to speak, but

without avail. At the end of three weeks he succeeded in saying "mamma," in a slow, hesitating way, characteristic of a child first learning to talk. And in this way, learning one word after another, did he regain his lost, forgotten vocabulary.

The paralysis was more obstinate; yet after several weeks he began, by the aid of electricity, to perform slight muscular movements. Meantime his leg and arm were markedly atrophied. On first attempting to walk, his power of co-ordinating the locomotory movements was sadly in abeyance, his leg being thrown out "promiscuously." Yet in time this difficulty was overcome, and at the end of a twelve-month he appeared as sound and healthy as ever, having had no return of the fits.

The complete recovery of this case leaves the pathology of it in a state of speculation: yet it is rational to infer cerebral hemorrhage and clot, induced by the eclampsia. The aphasia without the paralysis might possibly be accounted for without supposing so grave a lesion, for he was manifestly aphasic from loss of memory. He never talked at random, and when once he had begun to learn his words over again they came readily enough to use. The writing-test was impracticable, of course, in so young a child.

The other patient not only had lost her power of speech, but the *intellectual faculty* that prompted written and spoken language was destroyed. If she could speak a word, she could not convey an idea with it. The child, as soon as it had the word at its command, used it correctly.

The woman's first attack would seem very much to have resembled the child's, though much slighter. Then she had simply forgotten her words. She could neither speak nor write. When this power was regained she could speak and write as well as ever. Hence the difference would apparently seem to be one of degree, for a second attack, more profound, left a far deeper impress upon the cerebral functions.

May not the child be predisposed to another attack of the same trouble, and liable to much more lasting damages therefrom?

SPONTANEOUS CURE OF A HERNIA.

BY JOSEPH R. BECK, M.D.

ON the 26th, of May, 1873, I was sent for to see Miss B. P., 15 years of age, for some trouble in or about her right groin. Upon making an examination, there was apparent a large, complete, right inguinal hernia. The history of the case was substantially as follows:

The patient, who is very large and muscular for her age, and prematurely developed, stated that some two weeks more or less before the time of my visit, in coming down a long flight of stairs leading from the school-building to the street, she somehow slipped, and fairly, though very forcibly, assumed a sitting position. The fall did not seem to be productive of any bad effect other than an undefined uneasiness, which was located in the right groin, and which disappeared after two or three days, and the circumstance passed entirely from her mind.

Two days prior to that on which I saw her,—namely,

on the 24th of May,—while lifting a tub filled with water from a bench to the floor, she states that she distinctly felt something give way in her right groin; and in the evening she noticed for the first time a tumor at the seat of pain. The pain, which had been acute from the time of the "giving way," had yet not been excessive, nor of such a nature as to have caused her any alarm; but this was the case when she saw the tumor, which, when she stood erect, was as large as a good-sized orange, but which became somewhat reduced in size when she assumed a recumbent position.

Upon being duly satisfied that the tumor was a true hernia, and upon attempting its reduction by taxis, I found it to be impossible to return the bowel, and, ordering a bladder filled with crushed ice to be steadily kept on the tumor until morning, made no further attempt at reduction at that time. Next morning the hernia was readily and easily reduced; but, before a proper truss could conveniently be obtained and applied, the bowel descended a second time, and remained down in spite of careful manipulation, resisting all my attempts at its return until the morning of the 29th. On this day, however, I succeeded in returning it to the cavity of the abdomen, applied and adjusted the truss, and left the case, supposing that everything was again in proper condition.

On the 9th of June following, I was again sent for, and then discovered, to my surprise, some small hard bodies, numbering in all, perhaps, four or five, situated immediately beneath the skin, and apparently upon the site of the external abdominal ring, and productive of so much pain that the girl was entirely prevented from using her truss. She was now, by my order, strictly confined to bed. These substances continued to enlarge gradually until the 1st of July, when they presented a coalesced condition in the shape of a tumor as large as an English walnut, very hard, irregularly nodulated, with the skin deeply congested over its entire surface, and entirely immovable.

Diagnosis.—Either a portion of the omentum or inguinal lymphatics in a congested state from the forcible dilatation of the hernial canal, or—which is perhaps most likely—irritated to inflammation by the pad of the truss. A careful examination failed to reveal the presence of intestine in the tumor, and the most rigid investigation failed to demonstrate the least permeability of the hernial canal.

In order to confirm my diagnosis, I asked my friend Dr. Gregg to see the case with me. His opinion was to the effect that the trouble was probably glandular, and coincided with my own as to its cause. Acting upon my confirmed view of the case, I ordered alternately the application of iodine and cantharidal collodion for five or six days, when, having set up an issue of pus, poultices were ordered, and continued without intermission until July 14, when the patient was discharged from treatment.

The tumor sloughed entirely away, and, the irritation having been of such a high grade, the product was adhesion of the sides of the canal: this channel was thus hermetically sealed, and the hernia permanently cured. After wearing the truss

a few weeks longer, as a precautionary measure solely, it was laid aside, and never resumed.

It is impossible for me to determine positively what the nature of the tissue was that underwent this inflammation, but it is perhaps fair to regard it as having been glandular and not omental, since the hernial canal was not itself swollen to any appreciable extent.

FORT WAYNE, INDIANA.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

CLINICAL SERVICE OF DR. H. C. WOOD.

ON THE USE OF CALOMEL IN FUNCTIONAL HEPATIC DISEASES.

PHYSICIANS are divided into two schools on this subject; one saying that calomel has no effect on the liver, the other saying that it has. Those of the latter opinion are certainly in the majority, and embrace in their number by far the greater bulk of the active practitioners. Those who deny the action of mercury on the liver found their opinion upon experiments on animals; but, though much of our advance in therapeutics has been derived from this source, it cannot overthrow well-observed clinical facts.

Bennett, Gamgee, and others of the so-called "Edinburgh Committee" performed the experiments by making biliary fistulæ and giving calomel and other drugs. They found that calomel in small doses had no effect; in doses large enough to cause depression and other symptoms the amount of bile was diminished. But these experiments are unfair, because under abnormal conditions; and this alone would invalidate them.

Röhrig, a celebrated German author, opened dogs along the linea alba, drew out and opened the gall-bladder, and observed the secretion, which was kept up for several hours. To dogs about to be opened he gave calomel, with the result of greatly increasing the flow of bile. But I think that all these experiments should be cast aside. The only evidence to be relied upon is clinical.

Any of you may take ten to twenty grains of calomel, and your stools will become green. Some say that this green color is due to the formation of a sulphuret of mercury. I am not aware, however, that this has ever been proven for a single stool; and the question is not, Does *any* green calomel-stool contain mercury? but, Do *all* such stools? The evidence is most positive that many of the green stools of mercurial purgation contain no mercury in any form. Thus, Simon analyzed such fæces, and found biliverdin and the other normal constituents of the bile, but no mercury; and Golding Bird and Michea did the same, with much the same result. Now, to find mercury is a very simple chemical problem, and it is impossible that the metal should have been overlooked by such eminent chemists as those mentioned, especially by Simon, a prince among organic chemists.

By some it has been thought that mercury simply causes bilious stools by increasing peristaltic action and sweeping out of the small intestines the bile naturally there present. I cannot believe this: it is notorious that resinous purgatives—drastics, far more active than calomel—do not produce "bilious stools." This clinical observation of every day has been confirmed by the chemical researches of Michea, and is enough of itself to indicate that calomel increases the secretion of bile. But still more cogent reasons are

manifold for believing in the hepatic action of the drug. It is not rare to find persons whose livers are especially sensitive to the action of mercury; and in these I have known a moderate dose of the drug to cause not merely violent bilious diarrhœa, but also the vomiting of large quantities of nearly pure bile.

Moreover, the history of disease and of its treatment seems to me to prove indisputably the truth of the view I am advocating.

It is a well-known fact that in jaundice from obstruction the stools are almost white; and it has been over and over again experimentally proven that if in animals the bile be shut off from the intestines the stools lose their color.

You will often hereafter meet with cases in which slate-colored stools are passed, either with diarrhœa or constipation. This want of color is no doubt due to a want of bile in the alimentary canal, to a torpidity or absence of functional activity in the liver. If you give calomel to such a patient, you will find that the passages become black, or even green; and this may occur without any increase in the diarrhœa.

Many cases of serous diarrhœa, which have been treated indefinitely with astringents, etc., will be promptly cured by the exhibition of calomel.

To illustrate these points, I bring before you to-day these two men. I wish you distinctly to understand that the example I am about to give, although a striking one, is by no means a rare one; but the results mirror those which have been witnessed hundreds of times and which I myself have seen over and over again. The first patient entered the hospital four weeks ago; he then had ten to twelve liquid, colorless, slaty, painful stools daily; there was no vomiting. He was given at intervals opium, bismuth, acetate of lead, tannic acid, and nitrate of silver, and his diet was regulated *secundum artem*. Under this treatment he improved very slowly, and continued to have liquid stools and to be utterly devoid of appetite for nearly three weeks, when the color of his passages gradually changed, and he is now just fairly convalescent.

This second man was admitted at the same time, from the same locality, and with exactly similar symptoms. For ten days he had similar treatment, without decided improvement. The astringents were then stopped, and he was put on blue mass, gr. ix daily, in three doses: in two days the stools were firmer, much less frequent, and, what is more important, their color was changed; on the third day the man was well.

The symptoms in the two cases were exactly similar; the disease had originated under precisely similar circumstances and causes; both patients being paupers in the out-wards, doing the same work, or rather enjoying the same idleness, eating at the same table, and having similar constitutions and similar past histories; yet one required three weeks of treatment without a mercurial, and the other, after pursuing a similar course as its fellow for ten days under the same treatment, is arrested in twenty-four hours by calomel *without* astringents.

These cases, gentlemen, are very strong in their contrast, but, I repeat, are not solitary ones, but examples of what I have seen over and over again. Diarrhœas apparently trivial resist treatment until you give calomel. Sometimes the mercurial suffices; often, however, after the biliary secretion has been started, it is necessary to use for a day or two bismuth and acetate of lead, or other astringents. The practical bearing of these remarks is that you should always inspect the stools, and, if they indicate the absence of bile, calomel should be given unless especially contra-indicated.

You will find sometimes that slate-colored stools and digestive disturbances coexist with constipation; and under these circumstances a mild mercurial course

is often of great benefit. Again, sometimes green stools in adults replace the slate-colored passages of the diarrhœa of which we have been speaking: in such cases there is often excessive pain, especially if the diarrhœa has been stopped. Under these circumstances I have never found anything but a mercurial to act efficiently.

TRANSLATIONS.

THE CAROLINA TWINS IN PARIS.

AT a recent *séance* of the Académie de Médecine (*Bulletin de l'Académie*, February 13, 1874), M. Tardieu reported the result of an examination made by himself and M. Ch. Robin of this interesting case. His conclusions were that the double being is in reality formed of two distinct individuals, placed back to back and united by the bony framework of the sacral region. The spine, he remarked, shows in each individual a very pronounced double curvature, the result of efforts made by the two sisters at an early period of their existence to turn themselves face to face.

The superior parts of the bodies live an entirely distinct life; the heart occupies in each its normal position, and does not beat in unison with that of the other.

Tactile sensibility is entirely separate in all the superior part of the body; each individual separately receives and perceives different impressions. The most striking point about the lower part of the body is the community of sensation and tactile sensibility: the pulse carefully counted in the popliteal space presented a perfect synchronism. As to sensibility, it sufficed to touch any part of either of the four inferior members in order that both sisters should be simultaneously conscious of it. MM. Tardieu and Robin were assured that menstruation is always single and simultaneous, and that the need of excretion is felt and is always satisfied at the same time, in each of these creatures.

M. Tardieu having completed his communication, M. Broca remarked that he had also examined the twins, and, while not intending any criticism on M. Tardieu's remarks, he desired to call the attention of the Academy to certain peculiarities which seemed worthy of consideration. M. Tardieu had rightly said that the sensibility, which is completely distinct in the trunk and upper limbs, is common to both inferior members. He (M. Broca) thought, however, that it should be added that this nervous continuity is very limited. When the leg of one of the twins is touched, the other perceives a sensation, it is true, but cannot distinguish its character, nor the locality at which contact has been made, nor the extent of surface touched.

This very vague sensation never rises to pain, and contrasts strongly with the very decided sensation which is perceived by each brain when the corresponding legs have been touched.

In addition, the muscles of either sister obey only the corresponding brain: the will of one is incapable of exercising any influence upon the movements of the other.

The exact co-ordination of the movements of walking has undoubtedly been attained by habit only. It must then be admitted that the fusion of the spinal cords is limited exclusively to the posterior columns, and that even there it is quite incomplete.

Considering them as a single monster, as they stand twisted partly side to side, they may be said to have but one anterior and one posterior aspect, and consequently two weaker and shorter anterior limbs, and two stronger posterior. Walking is possible without the use

of the anterior feet, only the posterior touching the ground; a sort of ambling gait is the result. A similar atrophy of what may be called the two anterior members has been noticed in other double monsters.

They have in reality but one anus, and the rectum is simple, at least in its inferior part; the Y-shaped bifurcation which makes communication with the two digestive tubes is effected beyond the limits which can be reached. The single anus is situated between the members which have been called anterior.

The vulva is placed horizontally between the origins of the four limbs, on the inferior face of the united pelvis.

This vulva, although single in appearance, is in reality double. It has the form of an ellipse, terminating in a point at each extremity, and having at each extremity a clitoris with its prepuce. There are four labia minora, but only two labia majora, making the entire circuit of the vulva and corresponding to a single vestibule.

A median vertical antero-posterior septum separates, M. Broca was told, the genital apparatus of one from that of the other.

There are two vaginæ bordering on a single vestibule; to each vaginal opening a distinct membranous hymen was found. Finally, there are two urethras, situated one at each extremity of the vulva, between the corresponding hymen and clitoris.

This disposition conforms to that which has been previously noted in the case of similar monsters.

The existence of a double vagina proves that there should be two uteri. The genital apparatus is doubtless constituted like the intestinal,—that is to say, it is really double, and only joined towards the external orifice.

The fact of a community of function in the genital, urinary, and intestinal apparatus cannot be brought forward to prove a more complete fusion of these.

The community of circulation explains sufficiently the fact that the menstrual epochs of the sisters coincide perfectly.

It can easily be understood why defecation is simultaneous. The two sisters always eat together, and equally; it is quite natural that their two parallel digestions should terminate at the same time. Every one knows, moreover, that will and habit are capable of regulating to a certain degree the time of defecation. The will governs the functions of the bladder still more easily, since micturition may be retarded by its means for hours. It is unnecessary, then, to explain the simultaneous micturition of the twins by the theory of a common bladder.

M. Tardieu had remarked that the movements of the two hearts are perfectly independent, and that the radial pulses of the two sisters are not synchronous. It should be added that they are not-isochronous.

One of the hearts—that of Milly—beats always a little more rapidly than the other. The difference is about two pulsations per minute. Several observations showed the same difference.

He had not, said M. Broca in conclusion, been able to examine the pulsations of the pedal vessels; but many observers had noted that, contrary to the fact noted in the radial pulse, they are synchronous. This would incline one to the belief that the two arteries communicate largely between themselves in the pelvic region. A simple transverse anastomosis would not suffice at all to produce this result, and it is very probable that an anastomosis by convergence exists, below which the aorta bifurcates again.

M. Tardieu remarked that he placed but little confidence in the statements of a double vagina, etc., made by the attendant of the twins, and regretted that he had not been permitted to make any examination.

M. Broca, in answer to a question as to the existence of a single or double uterus, replied that he thought there were two.* A. VAN HARLINGEN, M.D.

REMARKABLE RECOVERY FROM ABDOMINAL SECTION

(*Boston Medical and Surgical Journal*, February 19, 1874).—Dr. David W. Cheever reports the case of a young woman who suffered from a large sarcomatous tumor, involving the peritoneum and the abdominal parietes. An operation for its removal having been decided upon, a vertical incision, about six inches long, was made two inches to the right of the umbilicus, together with a transverse incision four inches in length. The peritoneum was found adherent to the under surface of the tumor. In continuing the operation the rectus muscle on the right side was quite destroyed; on the left it was not much disturbed. A strip of peritoneum, fully four inches wide at its widest part, and perhaps six inches long, tapering down at its extremities, was removed with the tumor. The abdominal cavity was now largely uncovered. The colon and stomach, as well as the small intestines, were visible. As quickly as possible, two large, warm sponges were put in the site of the tumor, and the hernial protrusions repressed. Warmth was applied to the chest, and a brandy enema given. The patient vomited, but soon rallied. A considerable time was consumed in securing vessels all around the incision, of which a great number had to be tied, including the epigastric artery. The cavity of the abdomen was sponged free of clots, and long, deep, silk sutures were passed. It was impossible to bring the peritoneal edges within two inches of each other in the centre of the wound. The ligature-ends were all brought outside, and a separate set of sutures closed, without tension, the three flaps of skin, which had been dissected off the deeper parts of the tumor, where it was not incorporated with the skin. Broad adhesive strips were firmly applied; then cotton wadding and a binder. The patient was immediately lifted into a warmed bed, between blankets, and one-fourth of a grain of morphia was given subcutaneously. Her pulse was excellent. There was some tympany for two days, and from the third to the seventh day a thin, dark, offensive discharge came in quantities from the wound. Brom. chloralum was used as a disinfectant. The urine was drawn for ten days, and the bowels moved after two weeks. Menstruation came on in seven weeks, and six months after the operation she was well, riding about and doing ordinary house-work. The unfavorable elements in the case were—the shock of a large uncovering of the abdominal cavity; the loss of a broad strip of peritoneum; the closing in of the peritoneal cavity with the raw surface of the dissected skin; the presence of a multitude of ligatures; the chance of hemorrhage; and the necessity of suppuration.

CASE OF PURULENT INFECTION AFTER EXTRACTION OF A TOOTH (*The Dental Cosmos*, February, 1874).—A man of strong constitution had recourse to a horse-farrier for the extraction of one of the last left molars. The gums were violently contused, and a fragment of the alveo-dental periosteum torn away. A few days after, the following symptoms occurred: headache, insomnia, fever, horrible fetor of breath, inflammation of the left cheek and gums, with formation of an abscess. Notwithstanding energetic treatment, the patient died two or three days later.

* A very full account of these twins, accompanied by a photograph and wood-cuts, appeared in the *Photographic Review*, vol. i. p. 43, 1870-71. The author of that paper, Dr. William Pancoast, was enabled to make a careful examination of the genitalia, and his observations show, in contradiction to the theory put forward by M. Broca, the existence of but a single uterus. In other respects the observations of the French physicians agree in the main with those of Dr. Pancoast.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

EDITORIAL.

LEGISLATION FOR THE INSANE.

CAN any one tell us by what fatality it is that amateur philanthropists and the chosen legislators of the State, when undertaking to promote the interests of the insane, frequently seem to have as completely lost their wits as the poor creatures who have awakened their sympathies? Certainly, the total ignorance of insanity and the ways of the insane, the palpable absurdity, the gross violations of common sense, that mark many of their performances in this direction, would be scarcely conceivable without the testimony of actual experience. During the last half-dozen years, many of our States seem to have been endeavoring to outdo one another in absurd and mischievous legislation for the insane. That demagogues should find it a sure card to clamor about tyranny, and wrong, and people's rights, and that amiable men sincerely anxious to do good should be instant, in season and out of season, with their pet schemes for accomplishing some unwise, if not impracticable, project, is what might be expected in the ordinary course of things; but it is surprising to see how readily, in a matter of so much importance, involving the peace of families and the safety of individuals, legislators stultify themselves by enactments pre-eminently foolish.

A few years hence, it will become one of the curiosities of human credulity that, in the seventh decade of the nineteenth century, a poor crazy woman, relying only on her nimble tongue, visited the legislatures of several of the States, and per-

suaded them to pass an act, framed by herself, for the government and surveillance of their hospitals for the insane; an act ignoring every principle of moral management supposed to be established by the experience of men enlightened by the science and imbued with the humanity of the age, and fitted only to introduce into those abodes of peace, quiet, seclusion, patience, and trust, a state of perpetual restlessness, anxiety, irritation, and distrust. Although these institutions are controlled by Boards of Trustees or Managers, comprising men whose character entitles them to unlimited confidence, yet her project provided another board, entirely independent and uncontrolled, and armed with plenary power to visit the hospitals whenever they pleased; to enter every hall and room, unaccompanied by any officer of the house; to hear every patient who had any complaints to make; to call before them the attendants, and sit in judgment on their conduct as represented by the patients, and to discharge both patients and attendants, without let or hindrance from any other authority. To inspire the patients with distrust of the officers, and withdraw them, as much as possible, from their control, a letter-box is to be placed in every hall, into which the patients are directed to drop their letters, sealed; and the officers are bound under heavy penalties to stamp and forward them, unopened, to whomsoever they may be directed. Letters to patients are also to be delivered unopened.

An act embodying these provisions was passed by the legislature of Iowa a year or two since, and by that of Maine, if we are not misinformed, the present winter. We are glad to say that in some other States where this woman has labored she has not been so successful, although, with that sort of glamour which bewilders so many persons of deranged intellects, she imagines, and so represents, that she has never failed. What the result has been in Iowa we learn from the reports of Dr. Ranney, the late superintendent, and of Dr. Bassett, his successor, premising that the former, after a service eight years long, highly creditable to himself and incalculably valuable to the hospital, resigned in disgust. He says that the authority of the officers was superseded by another, guided by no knowledge of insanity and working under the profound conviction that every officer and employé of the hospital was abusing his trust; that the latter soon came to be regarded by the patients as their natural enemies and oppressors; that all the salutary influences springing from their proper relations to each other were destroyed; that the habit of writing letters, and expecting replies that did not

always come, produced in the patients a state of chronic irritation not very favorable to recovery; that friends were alarmed by their stories of abuse; that the time and temper of the officers were taxed beyond endurance in replying to the anxious inquiries and complaints thus produced; that the best attendants refused to remain where they were perpetually charged with wrong-doing and condemned without a fair trial; and that many a patient was prematurely removed, to drift, very likely, into chronic insanity. Dr. Bassett testifies to the same results, and speaks particularly of the evils arising from the unrestricted correspondence. To any person possessing the faintest sense of propriety or the smallest modicum of common sense they are shocking enough, but to the average legislator, no doubt, they are the welcome outcome of a blessed reform. During the eighteen months that the law had been in operation, 5876 letters were sent to the post-office, and about as many were received by the patients. The character of the latter would scarcely be imagined by any one not practically conversant with hospitals for the insane, and therefore we quote Dr. Bassett's statement at length:

"Kind-hearted but injudicious friends have not unfrequently imparted news to patients, of an unfortunate character, at an untimely period, with such results as to have undone in a moment all that by patient labor and watching, extending over a period of weeks or months, had, by slow degrees, been accomplished. In a good many instances money has been sent to patients who did not need it, and who could not use it, which has been an inducement to elopement, and has resulted in efforts to get away from the hospital which would not otherwise have been made. I hold in my possession a package of opium sufficient in quantity to destroy life, if taken at a single dose, recently sent in a letter to a patient who, a week before his admission, had attempted suicide by cutting his throat. He had written to his friends that he was restless at night, and could not sleep, and wanted 'something to quiet his nerves.'"

The legislature of our Commonwealth has committed no folly exactly like this. It has placed no letter-boxes in the halls of the hospitals, and no case of suicide from opium can be fairly charged to its account. But it has made it a penal offence for the officers to withhold any letters of patients addressed to their counsel,—meaning thereby any one they happen to hear of as a lawyer,—or to debar the latter from seeing and conversing with the patients, if they wish it. The act is of little importance, because, with the kind of freedom now enjoyed

by the inmates of our hospitals, letters may be written and smuggled out every day in the week; and lawyers enough will be found ready to "take hold," provided they can see any money in it. The patient may have nothing, but his friends may do the handsome thing rather than be dragged into court to reveal the troubles and trials of the family. Revolutions, it is said, never go backwards: so in the fulness of time we may have here letter-boxes in the halls, whereby men of proverbial wisdom and prudence will proclaim their follies to a jeering world, and women, delicate, refined, and modest,—wives, mothers, sisters, daughters,—moved, as they often are in insanity, by the coarser feelings of their nature, will reveal their inmost thoughts in a manner the consciousness of which, on recovery, will overwhelm them with mortification and dismay. This is shocking, no doubt, to every person of any propersensibility; but let the public advance a little further in its contempt for all special knowledge, and be more ready on any matter of insanity to follow the lead of crazy women and amateur reformers, rather than the counsels of those who have made it the study of their lives, and we shall be following the example of Iowa and Maine. Follies of the kind we have been describing we shall always have, so long as people talk of what they know little or nothing about, and, under pretence of righting some great wrong or reforming some flagrant abuse, obtain ready credence from those who know as little about it as themselves.

THE COMPLIMENTS OF THE SEASON.

WE have been somewhat surprised at a furious attack in the *Medical and Surgical Reporter* of February 28, upon the *Philadelphia Medical Times*, particularly upon its Siamese Twins number,—an attack provoked, apparently, by our offering our readers a phonographic account of the report of the Commission to the College of Physicians. The lethargy of our ancient and venerable cotemporary would not, it seems, permit of the enterprise required to publish a full report of a meeting within twenty-four hours of its occurrence; but, this being the case, the *Reporter* would certainly have better consulted the dignity of its age and feebleness by maintaining silence, especially since in the same number it publishes an editorial in which the facts are taken without acknowledgment from our columns, as is shown by the circumstance that out of the two mistakes which occurred in our hasty report of Dr. Pancoast's and Dr. Allen's remarks, one has been copied, its utter ridiculousness not having been perceived by the

astute compiler. When a friend—or, if it suits the *Reporter* better, a rival—has achieved a success, it is much better policy to keep quiet than to raise a cry whose universal echo must be “sour grapes.”

Ill humor or impotent rage may afford amusement to lookers-on, may lead to the firing of a columbiad at a sparrow, or to the discharge at the innocent editorial caput of the *Philadelphia Medical Times* of a sentence containing eight words averaging thirteen letters apiece, but it is usually as destructive of logic as of good English; and the present instance is seemingly no exception to the rule.

Our critic tears passion to tatters because we do not hold ourselves bound by the Code of Ethics which the American Medical Association imposes upon its members. Not to be able to recognize the difference between a medical journal and a “medical practitioner” bespeaks a rare and choice obfuscation of intellect, which is delightful in an age surfeited with “cuteness.” A doctor does not advertise legitimately; a medical journal advertises legitimately in every way. The difference is so plain that it is a hopeless task to explain it to any one who does not see it at once. We give it up: our friend the editor of the *Reporter* must excuse us. Because we object to doctors advertising, and do advertise the *Philadelphia Medical Times*, with charming simplicity does our friend hurl at us that grand old maxim of our grandmother’s sampler, “Consistency, thou art a jewel!” We might retort that the jewel would shine fairer in the coronet of our virtuous critic if recently the whole country had not been deluged with circulars of the *Reporter*; but we desist: with pleasure we let the little animal—the *ridiculus mus*—creep into the oblivion of to-morrow. One request we would make of our assailant: hereafter, in attacking us, please do not sacrifice truth to indignation, and please do not misstate facts.

DROPS AND DROPPERS.

HAVING had occasion recently to keep a patient narcotized, and using the *deodorized* tincture of opium, we were astonished to find that the liquid disappeared from the bottle much faster than was to be expected from the number of drops exhibited. The phial used was the ordinary ounce-bottle of the apothecary. On dropping into a minim-glass, we found that it did not take, as usually estimated, one hundred and twenty drops to make up the drachm, but that *fifty-two* sufficed to do so. Deodorized—or, as it is sometimes called, denarcotized—laudanum

differs from true laudanum in being largely a watery preparation; and although its strength is practically the same, measure for measure, as that of the older preparation, its power, drop for drop, is evidently twice that of the ordinary laudanum. Yet we think most of the profession are in the habit, as we certainly have been, of giving twenty-five drops as the usual dose.

While on the subject, we take the opportunity of anathematizing those popular and plausible instruments,—the so-called “droppers.” As is well known, they consist of a pointed glass cylinder and a minute india-rubber bulb. Owing to the fineness of the point to which the liquid adheres, the drop is excessively small. Thus, using the deodorized preparation just spoken of, we found that one dropper gave one hundred and ninety-six drops, another one hundred and eighty-five drops, to the fluidrachm: in other words, the drop from the new apparatus was only one-fourth of an old-fashioned, honest drop. Evidently, if we are not to drop drop-doses, we must drop dropping from droppers.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JANUARY 22, 1874.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

DR. GEORGE A. REX presented a specimen of *congenital malformation of the heart, contraction of the pulmonary artery, deficient septum ventriculorum, with origin of the aorta from both ventricles, no cyanosis*, from Matthew B., æt. 6 years. There was no history of any acute attacks of cardiac disease, but from an early age there had been signs of an embarrassed circulation, without any cyanosis.

Physical examination showed markedly extended impulse of the heart, with the apex-beat at the fourth rib just below the nipple; it was accompanied by a strong thrill.

On auscultation at the base, a strong systolic murmur was heard, which was transmitted to the apex, and was also heard over the pulmonary artery and along the aorta into the large arteries.

Three weeks before death, several hemorrhages from the lungs took place. General œdema set in, with effusion into the pleura, causing embarrassed respiration which lasted until death.

On post-mortem examination there was found considerable effusion into the pleural cavities, with little or none in the pericardial sac.

There was extreme hypertrophy of the walls of the right ventricle; while the left ventricle was small, with comparatively thin walls.

The aorta was healthy, and its valves were well formed and healthy; but it was situated immediately over the septum of the ventricles, which was imperfect, so that the aorta communicated directly with both ventricles. The cavity of the left ventricle was in great measure occupied by a firm clot, so that it evidently

had taken but a small part in carrying on the circulation.

The orifice of the pulmonary artery was contracted, and its valves contracted and adherent, so that but a small slit-like orifice remained, through which the blood could pass only with difficulty. The ductus arteriosus was closed. The valve of the foramen ovale was large enough, but was unattached at a small point, leaving a communication between the auricles as large as a goose-quill.

The PRESIDENT said he had had the opportunity of examining the case during life. The little boy was suffering very severely from disturbance of the heart's action; the pulse was very frequent,—140,—and there was a much more marked murmur than usually attends these cases of malformation. As a rule, the murmur was not intense, and was heard most distinctly over the locality of the perforation between the septum of the ventricles. In this case it was clearly a pulmonary artery murmur, and was transmitted from the base of the heart upwards to the left of the sternum, and the point of greatest intensity was along the left border of the sternum. It was also transmitted somewhat towards the right, and occupied the whole body of the heart: indeed, so intense was it that it could be heard over the whole chest and abdomen. This is to a certain extent explained by the patulousness of the pulmonary artery, which, while obstructed, still allowed the blood to pass.

Dr. O. H. ALLIS said he had a similar specimen, removed from a person 20 years of age; but, in consequence of the regurgitation, the right auricle had become so much dilated as to be capable of holding eight ounces of blood. He believed that in Dr. Rex's case there was no dilatation of the auricle.

The PRESIDENT presented a specimen of *rupture of the gall-bladder*, from Mr. A., æt. 70 years; of a healthy, long-lived family; had always enjoyed good health until the summer of 1873. For many years he had been of sedentary habits, and, although temperate in the use of stimuli, ate abundantly. About July last he began to be troubled with attacks of severe pain in the epigastrium, attended with vomiting, weakness, discoloration of urine, and distinct, though not extreme, yellowness of skin. These attacks were of short duration, but recurred every week or so. His general health did not seem affected severely, and the nature of his case was not suspected. In December he was seized with intense pain, referred to the right side of the back below the ribs, and to a point in front about midway between the gall-bladder and the umbilicus. The pain was very intense, and was moderated only by large doses of morphia. There was vomiting, with anæmia, constipation, and deep brownish-red discoloration of urine, which was found to be free from blood, but to contain bile-pigment. It was not tested for biliary acids. After twenty-four hours there was some remission in the severity of the suffering, when a second violent exacerbation occurred. The same partial relief occurred again in twenty-four hours, followed by a third intense paroxysm, during which he became slightly delirious and struggled to leave his bed. During his violent struggles against the strong restraint which was used to keep him in bed, he suddenly complained of still more intense pain in the right hypochondrium. He then soon sank into a state of collapse, with cold extremities, distended belly, which was tender on pressure, and wandering delirium. Death occurred fifteen hours afterwards, or about seventy-two hours from the beginning of the attack.

At the *autopsy* the abdomen alone was examined. There was general peritonitis, with fine injection of the membrane and adhesions of the coils of the intestines. On separating these, delicate ridges of soft lymph marked the lines of adhesion. There was a large amount of thick, grumous bile in the right hypochon-

driac region, lying free among the coils of the intestines close to the concavity of the liver. This organ was of full size, and in an early stage of cirrhosis. No lesions of the stomach, spleen, or kidneys were observed. The common bile-duct was greatly dilated, measuring about three-eighths of an inch in diameter. At a point one inch from the intestine a large conical biliary calculus was found impacted. About this point the duct was distended with bile, and on following up its ramifications throughout the liver they were found distended with grumous bile, containing numerous coarse, gritty particles of biliary gravel. The gall-bladder was collapsed, and contained only a round, black calculus, three-eighths of an inch in diameter. The walls were thickened and fibrous; the mucous lining was normal, save in one point, just at the beginning of the cystic duct, where there was a perforation which would admit an ordinary probe. The cystic duct was narrow and tortuous, but still patulous for fluids.

Dr. J. H. HUTCHINSON presented, for Dr. BODINE, of Trenton, a specimen of *aneurism of the aorta*, removed from a man aged 29 years, who was six feet high and weighed two hundred pounds. He died suddenly while at work in the shoe-shop of the New Jersey State Prison, where he had been for six years. He had had constitutional syphilis in a mild form. There were no symptoms of aneurism during life, and the disease was, therefore, unsuspected. He had been engaged during a part of his imprisonment in working one of the shoe-pegging machines, an occupation which is sufficiently laborious to have had something to do with causing the aneurism.

The PRESIDENT recalled a specimen of heart-disease presented by him several weeks ago, when, in addition to extensive disease of the aortic valves, there was a small aortic aneurism very similar to this, and which was not suspected before death, the physical signs being attributed solely to valvular disease.

Dr. C. B. NANCREDE referred to a large aneurism which he had presented last spring from a patient who dropped suddenly dead, who had previously suffered from secondary syphilis, and in whom aneurism was not suspected.

Dr. MORRIS LONGSTRETH presented a specimen of *cancer of the liver*, removed from E. W., æt. 35, a widow, domestic, admitted to the Pennsylvania Hospital November 18, 1873, and who died November 23, 1873.

She had been in poor health for five years, but was without distinctive symptoms of disease until last summer, when she had an attack of vomiting, with loss of appetite. Subsequently she had considerable pain in the abdomen; but this was not a prominent symptom.

On admission, the patient was extremely weak, and it was difficult to make an examination or to obtain any history. The abdomen was much enlarged, and in the right iliac fossa and umbilical region a large mass was felt. She suffered from vomiting; urine was albuminous, very scanty, and contained granular casts with fatty epithelial cells attached.

On the fifth day after admission she was in a moribund condition, and a pretty thorough examination was made. There was dullness from the fourth rib to a point ten inches below, nearly to the ilium. The lower border of the liver could be distinctly made out.

Autopsy, one hour and a half after death.—Body emaciated; no anasarca of cellular tissue.

Thorax,—a few adhesions of pleural sacs on both sides. Lung-tissue everywhere crepitant; near the apex of the right lung was a small calcareous nodule, surrounded by a congested area.

Heart and vessels were normal, except a slight thickening of the mitral valve and a few atheromatous patches in the aorta. *Lungs and bronchial glands* were blackened by a pigmentary deposit.

Abdomen contained a large amount of blood-stained serum.

Stomach was rather small, and adherent to the surrounding parts. On the lesser curvature were three or four much enlarged and infiltrated glands of soft consistency. These contained no fluid.

Projecting into the cavity of the organ and connected with the enlarged glands was a large granulating mass, fungus-like, with everted edges and a depressed centre. Its surface was uneven, but ulcerated at only one or two points slightly.

Liver was enormously enlarged in all directions, and weighed ten pounds three ounces avoirdupois; the peritoneal coat, though thickened in places, was generally smooth; the right lobe was constricted or depressed at the part corresponding to the costal border. There were no very prominent nodules on the upper surface of either lobe, but the under surface of the left lobe was considerably nodulated. The lower border of the organ was firm, and generally even. There was no umbilication of any of the nodules. The calibre of the vena cava was somewhat encroached upon, and turned from its normal direction by the enlargement of the organ upwards and backwards. Transverse section of the left lobe revealed irregular cancerous infiltration of the hepatic tissue; the deposit was soft, and yielded little or no juice.

Gall-bladder was moderately distended with greenish bile; cystic, hepatic, and common ducts pervious.

Spleen was of normal size; a few patches of recent lymph on its surface.

Kidneys were of normal size; weight of both, ten ounces. Capsule transparent, and readily removable.

Uterus very small; as the size of a pin's head; probe entered about one inch; no cancerous nodules in any other parts.

Dr. J. H. HUTCHINSON said the patient had been under his care for five days. When admitted, she was in a very feeble and wretched condition, and it was very difficult to obtain a history. The existence of liquid was easily detected, but so much distention and tenseness of the abdominal walls was produced by the presence of a large amount of gas in the intestinal canal that a thorough examination of the abdomen was impossible. When he first saw the patient he felt very distinctly a mass in the right iliac region, but he also detected a clear sound beneath the costal border, and was unable then to trace the liver into the mass. He was therefore disposed to consider the latter an enlargement of the kidney or ovary. A few days later, when the distention was less, he was able to trace the liver from the costal border down to this mass, with which it was evidently continuous. Having recognized the enlargement of the liver, it was by no means easy to conclude that this was due to cancer. The surface of the organ was smooth, and there was very little jaundice. She had no symptoms pointing to cancer of the stomach, which existed.

Dr. H.'s impression was that the clearness referred to below the costal border was due to a distended colon. Frerichs has called attention to the fact that a coil of the small or large intestine occasionally gets between the liver and the abdominal walls and gives rise to this tympany; but he did not think that was the case here.

Dr. LONGSTRETH presented the *enlarged spleen and cirrhotic liver* from G. H., æt. 50; single; hatter; admitted to the Pennsylvania Hospital September 23, 1873, and died December 4, 1873. The patient denied that he was syphilitic or intemperate. He had had two severe attacks of malarial fever in Arkansas three years ago; otherwise he had been in good health until June last. At that time he had a very copious hemorrhage; he had subsequently been very weak, but there was no return of bleeding. Anasarca and ascites appeared shortly afterwards. No urinary symptoms were noticed.

On admission, spleen was found to measure four inches in transverse diameter; abdomen distended; heart and liver displaced upwards. On October 6, vomited blood,—about eight ounces; and this recurred several times.

November 4.—Abdomen increasing in size; some decrease in hepatic dulness found. Splenic dulness began as high as the fifth rib. Microscopically it was thought the blood showed an increase of white blood corpuscles. Stomach had become very irritable.

November 27.—Two gallons of fluid were drawn from the abdomen.

Died December 4, from exhaustion.

Autopsy, made two hours after death.

Thorax.—No morbid appearances to note.

Heart.—Organ was small, and its left ventricle was somewhat hypertrophied.

Abdomen contained a large amount of fluid, it having nearly refilled to its original size after the tapping.

Liver was contracted, hob-nailed, and fissured in places, and weighed three and a half pounds. The fibrous tissue was increased; abundant oil-globules were seen; cells reduced in size, very granular and fatty,—indeed, no cells could be found normal in appearance. On upper surface was a small but deep-puckered depression, from which nearly all traces of cell-structure had disappeared, nothing but the fibrous elements being present, with the interspaces filled with blood, which escaped on section. Connective tissue in the fissure was increased and opaque.

Gall-bladder contained greenish bile; its duct was narrowed, but patulous.

Spleen was enormously enlarged, weighing three pounds avoirdupois. The organ rested nearly horizontally under the diaphragm. It had several deep fissures running across its outer surface, and from its upper extremity was a large, projecting mass. Capsule thickened, and trabeculae very prominent. Its tissue appeared mottled, and under the microscope its granular and corpuscular as well as fibrous and elastic tissue were found enormously increased.

Kidneys were considerably increased in size, and very firm; capsules were quite adherent, and on removal left a granular surface. The organs were very much congested, but their outline was regular. A small cyst was found on the outer edge of the left kidney. Under the microscope the epithelial cells of the tubes were found quite granular, but not fatty, and no casts were discovered.

Dr. LONGSTRETH also presented a specimen of *obstruction of the bowel*, from the body of a young man who died shortly after admission to the Pennsylvania Hospital. He had been ill on board ship about ten days, with obstinate constipation, apparently arising, so far as the history could be obtained from his friends, from some obstruction of the bowel, but had received no treatment.

At the autopsy, the upper two-thirds of the small intestine were found distended to about the size of the colon; the contents were fluid, and the coats congested. In the right renal region there was a sharp twist, the tube being bent directly on itself, and it was at this point bound by a slight inflammatory band, which prevented any movement of the bowel and maintained a perfect occlusion of the intestine. There were a few inflammatory adhesions in the neighboring parts, but these other bands did not seem to make such perfect obstructions as the one previously mentioned. The calibre of the lower part of the intestinal tube was much reduced in size. The colon contained considerable solid matter of a whitish color.

The PRESIDENT asked Dr. Longstreth whether the band was in such condition that by its section it was possible life might have been saved.

Dr. LONGSTRETH thought it was.

The PRESIDENT considered this a very important point to be noted, because cases of this kind of obstruction were not uncommon, and usually the seat of the obstruction was such as to render it accessible by a comparatively small incision through the abdominal walls in the left iliac region. Fortunately, several cases have been recently reported where the operation has been performed with success.

Dr. J. H. PACKARD presented a *basilar artery* from which there had been *cerebral hemorrhage*, removed from Miss H. L. C., æt. 73, who was found dead in her room, lying on her face, near the washstand, early in the morning of November 16, 1873. There were evidences of her having vomited just before her death.

She had been under his care in the summer of 1872, with symptoms of hypochondria, no physical cause being assignable. Afterwards she was seen by Dr. A. H. Smith. At the time of her death she had been for some time under the care of Dr. J. C. Morris, on account of debility, insomnia, and hepatic derangement; but these symptoms had in very great degree disappeared, and she had, on the evening previous, seemed to be quite well.

By Dr. MORRIS'S request, Dr. P. made an autopsy, seventy-two hours after death. Present, Drs. Morris and Horace Williams.

Head.—Dura mater adherent to the calvaria. Arachnoid opalescent, with serous effusion everywhere beneath it. A very large clot of blood covered the whole base of the brain, the base of each anterior lobe, and the sides of the hemispheres, extending into the anfractuositities as well as into the third and fourth ventricles. The spinal canal also seemed to be full of clot.

The left vertebral artery was about four times the size of the right (enlargement of the left, or contraction of the right?). The basilar artery was of full size; Dr. Morris thought it dilated. Near its middle, on the left, was an orifice, by which the escape of blood had in all probability taken place. The cerebral hemispheres and cerebellum appeared on section to be normal; but the optic thalami, corpora striata, and crura cerebri were decidedly softened. The lateral ventricles were full of bloody serum, and the choroid plexuses distended with dark clot.

Thorax and abdomen.—Costal cartilages ossified; lungs entirely non-adherent and normal, but presenting some hypostatic congestion; heart healthy, although slightly softened; valves normal, aorta very slightly atheromatous just at its root.

The space between the layers of the lesser omentum was filled with a mass of solidly coagulated blood, which extended up along the œsophagus, gradually becoming more and more slender, to a point about three inches above the diaphragm. At this point a vessel must have given way; but there was no ulceration or other visible cause for hemorrhage, nor could the vessel itself be detected.

The liver was enlarged, fatty, and in an early stage of cirrhosis; the kidneys were simply congested.

The uterus and ovaries were extremely small; the left ovary especially.

The PRESIDENT asked whether there might not have been injury to any of the abdominal viscera in the act of falling, since the occurrence of large intra-peritoneal hemorrhage following injuries to the abdomen is sufficiently familiar.

The PRESIDENT asked Dr. Hutchinson whether hemorrhages from the basilar artery were not rare.

Dr. HUTCHINSON replied that they were rare, and that, were it not for the difficulty of accounting for the hemorrhage in any other way, he should think the rupture must have occurred in the removal of the brain.

The PRESIDENT said the pressure of the clot was

difficult to explain upon any other supposition than that of rupture.

Dr. PACKARD said he had used much care in removing the brain.

Dr. HUTCHINSON said aneurisms of the basilar artery were not very uncommon, there being at least twenty-five cases on record. In this case the artery appeared slightly dilated, but there was certainly no aneurism.

Dr. PACKARD further said that he had twice reported to the Society cases of hemorrhage from the œsophagus which had produced death. One was that of a man of intemperate habits, while the second was that of an old lady who had led a life of abstinence. In both there were erosions of the lower part of the œsophagus, in which the giving way of a vein had produced enormous and fatal hemorrhage.

Dr. R. M. BERTOLET exhibited sections from a *poly-poid tumor* removed from the *trachea per vias naturales*: a report of the case will appear among the original communications of a future number of the *Times*.

GLEANINGS FROM OUR EXCHANGES.

EXTRAVASATION OF URINE (*The Lancet*, January 17, 1874).—Mr. Wm. S. Savory believes that in cases of rapid extravasation of urine due to laceration of the urethra from a blow or fall on the perineum, the first step is to make free incisions into the infiltrated cellular tissue, wherever there is most evidence of mischief; always one or two in the perineum near to the point whence the urine escapes, two or more in the scrotum, and others elsewhere if required.

The escape of decomposed urine is almost always followed by great relief, and an entire change in the patient's condition. Suppuration and sloughing of the cellular tissue will necessarily follow, and will be extensive in proportion to the time which elapsed before surgical interference. No further measures are at the time called for, beyond poultices or antiseptic fomentations and nourishment, with stimulants, if needful, and perhaps opium.

Many surgeons introduce a catheter at once and retain it in the urethra, with the idea of giving that canal an opportunity of closing around it; but this plan is almost always productive of mischief. It has been said to prevent the subsequent formation of stricture at the point of injury; but it is very doubtful whether it has any such influence, while both its introduction and retention are very dangerous procedures. If the stricture does form later, as is almost invariably the case, the patient is in a far better condition for undergoing the operation of dilatation, or even of external perineal urethrotomy, than at a time when he is suffering from the effects of urinary extravasation.

POST-PARTUM HEMORRHAGE (*The Edinburgh Medical Journal*, December, 1873).—Dr. J. Matthews Duncan enunciates the proposition that uterine hemorrhage of the ordinary post-partum kind never takes place from the uterus when it is in a state of moderately firm general contraction.

He believes the following to be frequent sources of error: 1. Variations in the bulk of the empty and contracted uterus: an observer having a preconceived idea of the bulk of the empty uterus may, in an individual case, if judging from size, be greatly deceived. 2. Variations in position of the uterus after delivery. If the uterus has sunk into the true pelvis, it may appear small and contracted, when it is merely collapsed and depressed in the abdomen. If the uterus is high in the abdomen, which is often a consequence of repletion of the bladder, it may appear to be larger than it really is. 3. A uterus

may be hard and feel as if contracted, when the hardness is merely the result of passive tension. This is often seen in cases of hour-glass contraction, and of inversion. 4. Great and even fatal hemorrhage may be erroneously supposed to be ordinary post-partum flooding, when it is really running from an unsuspected source, as a perineal artery. Among such sources are injuries of the cervix, of the vagina, of the perineum, of the nymphæ, aneurismal bursting, so called varicose hemorrhage, uterine hæmatocele, etc.

ANTI-FEBRILE METHODS IN THE FEVERS OF CHILDREN (*Boston Medical and Surgical Journal*, February 12, 1874).—In typhoid fever Ziemssen uses a bath gradually cooled down, beginning with 95°, to 86°, and has often found that by diminishing the temperature to 83.7° the temperature of the child has been lowered two to three degrees for four or five hours. Jürgensen uses, in certain forms of pneumonia, a temperature of 86° lowered to 77°, of twenty minutes' duration, always obtaining a considerable reduction of heat for a relatively long time. In very severe cases, where the temperature is continuously high, or where it rises rapidly, as in typhoid fever, scarlatina, pneumonia, and certain cases of acute rheumatism, these moderately cool baths do not suffice, and more energetic measures become necessary. In his own child, the temperature rising rapidly to 104° after a bath of 66°, he did not hesitate to lower the temperature of the bath to 42.2°. In one hundred and ten cases of croupous pneumonia thus treated with baths, quinine, and wine, there were only four deaths, and in three of these the pneumonia was the sequel of other diseases. He always gives wine before and after the bath.

COUNTER-IRRITATION (*The British Medical Journal*, January 10, 1874).—The conclusions to which Naumann's experiments on counter-irritation have led him may be summed up as follows: 1. The therapeutic action of epispastics in general is accomplished through reflex paths and by the participation of the central nervous organs. 2. These means exert a distinct influence on the heart and vessels in proportion to the irritability of the individual; *a.* Strong irritation *lowering* their activity (weakening the cardiac contractions, dilating the vessels, and retarding the blood-current); *b.* Weak irritation *augmenting* it (strengthening cardiac contractions, contracting the vessels, accelerating the blood-current). 3. The part of the skin upon which the irritation is made to act is, for the most part, wholly indifferent. Variations in intensity alone influence therapeutic results. By increasing the irritation beyond a certain point we obtain a totally different kind of action from that with which we started.

BROMIDE OF POTASSIUM IN EPILEPSY (*The Practitioner*, January, 1874).—Prof. Binz details the following results, obtained by Dr. Clouston, in the treatment of twenty-nine insane epileptics with bromide of potassium:

1. The total number of fits gradually fell to one-sixth of their average number. 2. In one-fourth of the cases the mental state was greatly improved. Irritability and tendency to sudden violence were wonderfully diminished where they had been very bad. 3. None of the patients suffered in general health except five, in whom the ill effects produced were torpor of mind and body, drowsiness, increase of temperature, loss of weight, loss of appetite, and, in three, slight double pneumonia. 4. All the good effects reached their maximum in adults at thirty-grain doses three times a day: more than this seemed to do some harm.

TRANSFUSION IN POST-PARTUM HEMORRHAGE (*The Lancet*, January 17, 1874).—Dr. William Highmore suggests that in cases of post-partum hemorrhage, when

transfusion is indicated but when there happens to be no available source of blood-supply, the hemorrhagic blood of the woman defibrinated and warmed to the proper temperature would answer admirably for the emergency.

MISCELLANY.

TEMPERATE TEMPERANCE.—The only sensible attempt to solve the problem of the liquor-traffic, that we know of, is the Swedish one. Till recently, every family in Sweden could distil its own brandy, and paid no duty on it. Since the abolition of this privilege, and the consequent establishment of public houses, a united effort has been made, with the help of the government, to check the gross intemperance of the people. The number of public houses in a given district, the days and hours at which they are to be open, and the conditions under which they may sell, are all fixed by law, and the privilege of opening these is disposed of at public auction. An association of the friends of temperance buy the privilege, and keep these houses in their own hands. Pure liquors only are sold, and coffee and other beverages are to be had over the same counter. Rooms are kept pleasant and cheerful; innocent games and newspapers are furnished their guests, and every care is taken to make the place one to which the workingman can bring his family and meet his neighbors socially. On the other hand, it is the purpose of the managers to restrain rather than promote intemperance. The counter is not covered with raisins, pretzels, salt crackers, and other provocatives of thirst. Men are not pressed to drink, and the man who has had "enough" can have no more at that time. The net profits are expended on works of local charity.—*Penn Monthly*.

A FOREIGN contemporary records a fatal instance of the use of a uterine injection of perchloride of iron. Peritonitis supervened soon after administration, and death occurred in thirty hours.—*The Lancet*.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 3, 1874, TO MARCH 9, 1874, INCLUSIVE.

BAILY, E. J., SURGEON.—To report in person to the Commanding General, Department of California, for assignment to duty. S. O. 45, A. G. O., March 2, 1874.

BREWER, JOHN W., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Warren, Boston Harbor. S. O. 49, Military Division of the Atlantic, March 5, 1874.

GARDNER, W. H., ASSISTANT-SURGEON.—Assigned to duty at Fort Union, N. M. S. O. 34, Department of the Missouri, March 5, 1874.

WILSON, A. V., ASSISTANT-SURGEON.—Granted leave of absence on Surgeon's Certificate of Disability, for sixty days. S. O. 47, Military Division of the Atlantic, March 3, 1874.

CLEARY, P. J. A., ASSISTANT-SURGEON.—Assigned to duty at Camp Supply, Indian Territory. S. O. 34, c. s., Department of the Missouri.

MUNN, C. E., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Independence, Boston Harbor. S. O. 49, c. s., Military Division of the Atlantic.

SIMPSON, JOSIAH, SURGEON.—Died at Baltimore, Md., March 3, 1874.

SATURDAY, MARCH 21, 1874.

ORIGINAL COMMUNICATIONS.

THE ANATOMICAL, PATHOLOGICAL, AND SURGICAL USES OF CHLORAL.

Read before the Pathological Society of Philadelphia, March 12, 1874.

BY W. W. KEEN, M.D.,

Lecturer on Anatomy in the Philadelphia School of Anatomy.

I. ANATOMICAL USE.

IN August last, I think, I saw a scrap in a journal simply stating that chloral was an excellent antiseptic. I made no note of it at the time, and almost forgot it till I had a case of caries of the tibia (reported below) in which I desired such a disinfectant, and it occurred to me to try it. The result being satisfactory, when I came on duty at St. Mary's Hospital in October I tried it on a number of cases (some of which are reported below), and then tried the following experiments with it in my office with a view to its possible use in the dissecting-room.

Experiment I.—October 22, 1873, I placed some mutton with pure water in a bottle, corked it loosely, and stood it on my office table, exposed, say, to an average temperature, day and night, of 65°, as a comparative experiment. In four days it smelt very badly, and in seven was disintegrated.

Experiment II.—Same date. Mutton in a solution of chloral, gr. ij to f3j of water, and exposed to similar conditions. November 1 (ten days), slight mould. December 8 (forty-eight days), slight smell. December 25 (sixty-five days), entirely decomposed.

Experiments III. to VI.—Mutton placed in similar conditions October 22, 1873, but in chloral solutions of respectively 5, 10, 20, and 60 grs. to f3j of water. At this date, March 12, 1874, 141 days, or nearly five months, they are all perfectly preserved, with no smell save that of mutton-fat and chloral, no mould, no disintegration. A microscopic specimen from that in the five-grain solution is exhibited to the Society, to show that the muscular structure is perfectly preserved, as are also all the others.

Experiment VII.—A condyloma, removed December 24, was washed for twenty-four hours in water, and placed, December 25, 1873, in a forty-grain solution. It is still (March 12, 1874) perfectly preserved, and with the other specimens is exhibited to the Society for inspection.

Experiment VIII.—Feeling encouraged by some success, I obtained a foetus, still-born at full term, and injected it December 10, 1873, as follows: one arm, by the brachial artery (precautions being taken of course to limit the injection to the arm), with a five-grain solution; the other arm with a ten-grain solution; one leg, by the femoral artery, with a twenty-grain solution; the other leg with a forty-grain solution; and, by the umbilical cord, the trunk and head with an eighty-grain solution. I

used in all two ounces of chloral, and of each solution I injected as much as I could, so that the skin was fully stretched, as if the part were extremely dropsical. I had here a completely comparative experiment, for all the parts of the foetus were exposed to precisely similar conditions save the strength of the injection. I left it exposed on a table in a room of average temperature of 50° to 60° Fahr. March 10, just three months later, I examined it carefully. The body appeared perfectly preserved. The skin was shrivelled a little about the finger-nails, lips, eyelids, and scrotum, from evaporation; the toes were as plump as ever; the epidermis was slightly loosened. The head and neck, which were very much congested and discolored when received (a consequence, doubtless, of its being still-born), were of the same dark color, but no decomposition had ensued; and the common toilet-pins with which I had closed the incisions by which I reached the arteries were perfectly untarnished. On opening the parts injected with five-, ten-, and forty-grain solutions, and examining them, they appeared as firm as ever, all of natural color and consistence, and the microscope ($\frac{1}{2}$) showed no change in the muscular structure even with the five-grain solution. In order, however, to have a more careful examination, I gave Dr. J. G. Richardson a scrap of muscle from the ball of the thumb in the five-grain arm, another from the twenty-grain thigh; a slice of the tongue, which, as the mouth was open, had partly dried, but was covered with a cheesy coating (hence, probably, the torula reported below), and a piece of the parotid gland. He kindly examined them with great care, with a $\frac{1}{2}$ in. immersion lens, eye-piece A, giving 1250 diameters, and reports as follows:

"A small piece of muscular tissue from the palm of the hand (five grains), teased out in a drop of chloral solution, showed the individual fibres with remarkable distinctness, the transverse striations being unusually well defined, and the whole structure quite free from granular or other degenerative change. (The specimen was shown by the class microscope.)

"A similar fragment from the thigh, injected with a twenty-grain solution, was likewise admirably preserved.

"A thin section from the tongue exhibited muscular fibres in the same state of complete preservation; and in these, by the aid of acetic acid, the oblong and rectangular nuclei under the sarcolemma were clearly brought into view. A minute shred snipped out from the upper surface of the tongue displayed the filiform papillæ very distinctly, and furnished numerous cells of tessellated epithelium, presenting all the characters of epithelium in a drop of fresh saliva. Multitudes of isolated torula spores and a few short chains of torula accompanied this section.

"A thin section from the parotid gland showed the lobules of the glandular tissue almost unaltered, and, on the addition of acetic acid, the usual sharp definition of the nucleus in each gland-cell was obtained."

(An incision was made into one leg, and the above gross appearances were shown to the members.)

I have coated one arm with varnish and the other with rubber dissolved in benzole. I propose, after having exhibited it here to-night, to place one leg in a bag of saw-dust and the other in a bag of sand, and leave the remainder of the body exposed to evaporation during the next few months of hot weather. This will give me the means of determining whether the chloral will preserve the subjects in hot weather and of testing the best means of preventing evaporation. The results I will communicate to the Society in the fall of this year, whether they be good or bad, together with the results of any other experiments.

Experiment IX.—A negro subject was brought to my anatomical school February 23, 1874, in good condition as to preservation, but with the entire spinal cord removed, one leg off above the knee, and one femoral artery opened. It was therefore a very unfavorable subject to begin on, as so much of the solution must escape through, at least, the small arteries, which were cut. A half-pound of chloral, in the strength of 15 grs. to f3j of water, was injected by the carotid the same day. The body was placed on the dissecting-table March 2, and has been almost entirely dissected since then. The cuticle was very firmly adherent. The muscles were of the most life-like color, a little flabby perhaps, but not in the least easily torn. All the other parts, also, were of the natural color, texture, and condition, so that, for example, the aortic and other sympathetic plexuses were readily dissected. The odor of chloral was perceptible, but not at all offensive. March 7, the viscera were removed, and, instead of the usual fetid odor, which is so annoying, especially from its persistence on the hands, there was scarcely any smell. It was but slightly that of chloral, and was not disagreeable. This was twelve days after the injection. (Specimens shown.)

Experiment X.—A negro died in the city February 18, and lay exposed during the warm weather we had then till February 28, when he was brought to my rooms. The cuticle was off over all the chest, which was green and crepitant, and the legs were dropsical. A more unfavorable subject for preservation I have rarely had. Though a large man, I tried the chloral, on February 28, in the same strength and amount as in the last case, viz.: gr. xv to f3j. March 12,—i.e., twelve days after injection and twenty-two days after death,—the subject is perfectly preserved. The cuticle elsewhere is adherent, the chest is natural in color, the smell is gone, and the specimen of muscular tissue which I exhibit, though taken from the abdominal walls, the most unfavorable part of the body, is of admirable color and consistence.

The next subject I obtain I shall inject with one-fourth of a pound of chloral, and instead of the ordinary amount of water (a gallon to a gallon and a half), I shall dissolve it in not less than eighteen or twenty pints—that is, about five or six grains to 3j; for my short experience seems to show that if the parts are fully and most completely distended they are preserved better, probably because the chloral

penetrates more thoroughly into every minute capillary. In order to give a little more firmness to the muscular tissue, I shall also inject a pound or two of starch, dissolved in water and mixed with the chloral solution, and make a future report of the results.

It is important that I should not be understood to claim, as yet, that chloral will answer for the dissecting-room, to the exclusion of everything else. I have not had any experience beyond the mild winter we have so far had, and during a period of five months. What effect the hot weather of summer, with its moisture, will have, I cannot yet say, but hope to do so in the fall. Thus far I can claim for it entire superiority, in the winter-time, for all dissections, and especially for the finer and more delicate ones of the skilled anatomist. Its comparative merits may be summed up as follows:

1. *Cost.*—The price of chloral is about two dollars and fifteen cents per pound; and if one-half or one-fourth of a pound will do for each subject, the cost will be from one dollar to fifty cents for each subject. Chloride of zinc, or arsenic, costs about fifty cents for each subject.

2. *Condition of the tissues.*—Zinc hardens, discolors, and decolorizes the tissues to such an extent that, for both dissection and operative surgery, they are rendered totally unfit to give a student the proper notion of their normal color and consistence. Besides this, many parts, such as the axilla, with its entanglements of blood-vessels, nerves, muscles, glands, etc., important to be well dissected, are in such a discolored, dirty condition as hopelessly to bewilder the most earnest student. Alcohol is better than zinc, but it also hardens and decolorizes. Arsenic, also, is better, but the tissues become very soft and offensive in a little while, besides the frequent annoyance of local poisoning about the fingers. Salt and nitre subjects have the same objections (except the poisoning), and also nearly always mould in a short time. Chloral keeps the color perfectly, and the parts are of their natural consistence for at least three months, and probably much longer. By this means far more delicate and useful dissections can be made, and the student has a correct idea of the condition of the parts just as they were in life.

3. *Subsequent injections* into the arteries, etc., can be made with far better effect, since none of the arteries are at all contracted as they are by the astringent action of zinc; and the injection will therefore penetrate much farther.

4. *Permanent preparations.*—I have not yet had time to try this question, and so I do not know how it may act as to heat, moisture, vermin, etc.; but so far as finer dissections and finer injections are concerned, it would seem to promise well.

5. *Odor.*—The chloral odor, in a single subject, is not strong enough to be disagreeable, but how it may be with a roomful of them I am not prepared to say. I intend, however, to try the effect of some of the essential oils, such as cloves, bergamot, rosemary, etc., or a mixture of them; for a fragrant cadaver may entice some otherwise indifferent students to a more thorough study of its texture and tissues.

6. *Instruments and clothing.*—The destructive ac-

tion of zinc* in dulling the edge of the best knives, and thus worrying the dissector by the constant use of the hone, or, more frequently, making him careless and slipshod, is well known. Chloral does not affect the knives in the least; and even toilet-pins, after three months in the subject (Exp. VIII.), were not corroded in the least.

II. PATHOLOGICAL USES.

Besides the experiments detailed above, I asked Dr. Richardson to examine some pus, which I obtained from the Philadelphia Hospital through the kindness of Dr. Miller, on March 4, 1874. The following is his report, the examination being, as before, with the $\frac{1}{25}$:

"*Experiment XI.*—A specimen of pus from an acute abscess, preserved for six days in a five-grain solution of chloral, contained multitudes of well-formed pus-leucocytes, numerous dead (at least motionless) Bacteria from $\frac{1}{20000}$ th to $\frac{1}{2000}$ th of an inch in length, and considerable quantity of granular matter.

"*Experiment XII.*—A specimen of pus preserved six days in a twenty-grain solution presented precisely identical appearances; and since the Bacteria were about equally numerous, it seems probable that they had developed in the purulent fluid *before* it was mingled with the solution of chloral. On adding acetic acid or aniline to these specimens of pus, the ordinary reactions were manifested,—*i.e.*, the brightening of the nuclei or tinging of the nuclei and the cell-walls."

My own examination coincided with his.

Experiments XIII. and XIV.—I examined pus from a chancre, and also pus from an ulcer, with precisely similar results.

These experiments, as well as those given before, but especially the microscopical results as determined by Dr. Richardson and myself, at once suggest the query whether chloral in solution may not replace alcohol in the preservation of permanent wet preparations in our anatomical and pathological museums. It will be observed that the solutions varied from five to eighty grains in strength; the specimens were mutton, a condylomatous tumor, human muscular, epithelial, and glandular tissues, pus from an abscess, an ulcer, and a chancre; the time varied from six days to one hundred and forty-one days; the conditions were unfavorable for their preservation: yet not only were they all preserved macroscopically, but even the delicate cellular tissues were preserved microscopically; and, further still, the Bacteria already developed were killed even by a five-grain solution. Whether this preservative power will hold good for all sorts of wet preparations, for a longer time and in hotter weather, I do not yet know, but it will certainly do so for those named for five winter months, and probably longer.

If we can use it in place of alcohol we gain very greatly, first, in the lessened expense; for a solution of ten or twenty grains to the ounce is far less expensive than alcohol, and the bottles, instead of

being hermetically sealed, need only be closed by glass stoppers, or even by ordinary corks. Secondly, this renders them entirely accessible for study at any time, whether in investigating any particular subject or specimen or for exhibition to a class; and any teacher who has used permanent preparations, hermetically sealed in expensive bottles, which cannot be passed from hand to hand, which are distorted by the refraction of the liquid and the round glass, and not to be got at to examine accurately what we wish to study, well knows how comparatively useless they now are, and how useful they will be if chloral should make them accessible. If evaporation take place, the solution is meantime becoming stronger, for only the water and not the chloral evaporates; and an annual or semi-annual inspection of the museum, with the addition of either water or the chloral solution, will remedy any such trouble. I do not think that chloral in solution changes chemically within at least a year. I have used in some of my experiments solutions in water nearly six months old, and have had patients take the syrup from an old bottleful obtained a year before, without any perceptible change in its action.

In pathological investigations of various fluids, such as pus, urine, blood, the fluids in dropsy, etc., a few grains put into the fluid may be sufficiently preservative, and enable us to keep them for a much longer time for more careful observation. I would suggest that about five or ten grains to an ounce of the fluid would be enough; and it would be better to add it in crystals, for if added in solution it might change the specific gravity of the fluid, and so affect the integrity of the more delicate morphological elements. I would also suggest whether a solution of proper density—varying with the objects to be preserved—might not be of great service for mounting microscopical preparations. Neither of the last two suggestions have I tried myself, except with the pus, which has kept perfectly for eight days; but both are, I think, well worth the trial.

III. SURGICAL USES.

When I commenced my investigations into the action of chloral, I had seen nothing published but the little scrap which filled out a column in a journal, although since then I have seen several notices of its surgical applications.† Yet, as my observations are independent in character, confirm the results obtained by others, and show the value in surgery of a remedy as yet new, I venture to append a few of the more striking cases in which I tried it; in some with good results, in others bad. It acts, first, as a complete deodorant within a very short time, by what chemical action I do not know; secondly, as a stimulant, so that what was a foul, sluggish ulcer will become, in from two to three days, a fine, red, healthy, granulating sore. But it must not be used too strong, or it may become a decided irritant, as any one who has ever taken a dose would naturally expect. I have generally

* Zinc being our most common injecting material in Philadelphia, I use it mainly for comparison.

† London Lancet, August 30, 1873, p. 311; Amer. Jour. Med. Sci., October, 1873, p. 531, and January, 1874, p. 261; Med. News and Lib., February, 1874, p. 27; Phila. Med. Times, February 19, 1874, p. 326, etc.

found that gr. x to f3j of water (or, in private practice, some fragrant water) is quite strong enough. In some cases even this, which is about a two per cent. solution, is too strong, and has to be diluted. The results of the cases below were most marked in those with foul, unhealthy, ill-smelling discharges, which were changed quickly to healthy-looking sores, with excellent and yet moderate, not abundant, pus. In fact, in every case the discharge was, I think, considerably diminished. I did not find, I think, that the sores healed any more rapidly than they ordinarily would. The application seemed rather to change an unhealthy sore which was stationary, or even enlarging to a healthy one, in the proper condition for the healing process, which soon began and went steadily forward. In no case was its hypnotic action shown.

Whether it will at all destroy the specific poisons, such as that of a chancre, I do not know, for I had no opportunity to try it in the hospital. That it would do well in open buboes, as ulcers, I have no doubt; but the best test as to its possible destructive powers on the virus would be to try the auto-inoculability of a chancre which had been treated by chloral dressings.

I have found the mucous membranes also, as would naturally be supposed, more sensitive to its irritant properties than the skin, but not so much so in some cases as would be expected. In fact, I think it must be tested by experience in each individual case.

Cases I. and II.—One, a case of long-standing caries of the tibia, with very ill-smelling discharge; the other, of caries of short duration, but equally bad discharge. I used the chloral (gr. x to f3i) both as an external application, by which alone nearly all smell was prevented and discharge diminished, and later, in the same strength, as an injection into the sinuses. The injection did not irritate, but yet did no appreciable good other than the external application had already done, though continued for nearly a month.

Case III.—A case of psoas abscess (in which for four years the woman had worn a truss by a physician's direction, for a supposed hernia!). On admission, the abscess was discharging, in the groin, a very offensive pus in large quantities. A ten-grain solution was applied externally, and the odor completely disappeared at once, greatly to her own comfort, as well as that of the other patients in the ward. The discharge also certainly lessened, but I scarcely think it could be from the external application. It must have been from some other cause. As other injections had proved irritating, and she was rapidly sinking, I did not try the effect of an injection of chloral.

Cases IV. and V.—Two cases of large, filthy, and foul ulcers of the leg. I used a ten-grain solution as both a wash and a dressing; in one case mixed with a poultice, in the other simply by a compress, wet with the solution. The poulticed case did so well that all smell disappeared, the ward was freed from its previous contamination, and the ulcer did well. In the other case I had tried transplantation of skin, and four out of seven grafts had taken root. The continual application of the ten-grain solution on the compress was certainly too strong, for it not only destroyed the skin-grafts, but irritated the adjacent skin considerably. Generally, however, I have not found the constant dressing with the ten-grain solution too strong.

Case VI.—Rupial ulcers, of about the same size, on

the leg and arm. As a comparative test, I applied a ten-grain dressing of chloral to one, and touched the other with nitrate of silver, dressing it with simple zinc ointment. They did about equally well.

Case VII.—This was, I think, the best test of all, so far as the deodorizing properties of chloral are concerned. I do not say *disinfecting properties*, for I suppose that this is a question for the chemist rather than the surgeon. A young woman was infected by her husband with syphilis, and then he attempted a mercurial treatment. He so far succeeded that when she entered the ward, as I was making my visit, I found half of the teeth out, the rest ready to drop out, the gums sloughing everywhere, and necrosis both of the upper and lower jaw so far progressed that the upper jaw was loosening from all of its attachments. The smell was, I think, as bad as any I ever encountered, and the whole ward was filled with it in a very short time. I gave her a ten-grain solution of chloral as a mouth-wash, and on my visit the next day I could approach within six or eight inches before I was conscious of any odor. Yet the cause of the smell was constant, and the use of the wash intermittent. It was so grateful to her that she used it every fifteen or twenty minutes. The remaining healthy mucous membrane was not irritated. No hypnotic effect was visible from either absorption or the small amount probably swallowed.

Case VIII.—Gonorrhœa. In only one case of this kind have I tried chloral. I directed a one-grain solution, which so irritated the urethra that the patient would not allow its further use; but he was nervous about it, as I had inadvertently told him what I intended to use, and I scarcely trust his report. Parona,* however, reports an extensive use of it since 1870, in men and women, with the best results, in a strength of one per cent., *i.e.* about 5 grs. to f3i.

My friend Dr. Macpherson has tried it in several cases, and reports to me as follows:

Case IX.—Cauliflower excrescences of os uteri, with large hemorrhages and great fetor. During thirteen months he had tried numerous remedies. The only effective deodorant was potass. permang., and this, even in so weak a solution as gr. ½ to f3i, would irritate the parts so as to re-establish bleeding. He used chloral, gr. v to f3i. The odor was at once destroyed, no bleeding resulted, the discharge lessened greatly, and changed its character to good healthy pus; pain was relieved, and she became able to walk about in ten days.

Cases X. and XI.—Both of long-standing ozæna in scrofulous subjects. A solution of ½ gr. to f3i, by the nasal douche, proved irritating, and they were indisposed to allow further trial.

Case XII.—Syphilitic condylomata on the penis. The smell was almost intolerable from the mingled odors of the smegma and the condylomata. After washing with water, a ten-grain solution of chloral was applied, and the odor entirely removed. A slight balanitis occurred, which subsided on reducing the solution to 5 grs. The warts were removed, chromic acid was applied, chloral being used as a dressing, and the patient was well in four days, except one very small spot, which soon healed.

Case XIII.—Non-specific severe vaginitis in a child 4 years old, of strumous constitution. An injection and wash of 4 grs. to f3i was used, and no other treatment, and in two days the patient was nearly well.

Dr. Goodell also informs me he has used it considerably of late, and it does admirably as an antiseptic, deodorant, and stimulant.

SKIN-GRAFTING.

BY R. J. LEVIS, M.D.,

Surgeon to the Pennsylvania Hospital and to the Wills Ophthalmic Hospital.

THE operation of skin-grafting is now conclusively accepted as one of the resources of surgery. The utility of the transplantation of minute pieces of skin to granulating surfaces has been demonstrated in a vast number of instances. It is admitted that by creating centres of eccentric cicatrization on extensively ulcerated surfaces the rapidity of the healing process can be much increased. Ulcers of a chronic character, which have obstinately resisted cicatrization in a concentric direction, can be healed by the ingrafting of new centres of germination in the midst of the areas of ulceration. Experience has also shown that the procedure is applicable to plastic surgery, in facilitating the cicatrization of surfaces denuded by gaping, in the division of cicatrices, and in the sliding of flaps of integument.

Besides the increase in the rapidity of healing, due to extending the lines of cicatrizing edges, a decided and important physiological influence is exerted by the presence of the grafts on ulcerated surfaces. The surface of an indolent ulcer seems to be stimulated to renewed vital action, and the increased healing impulse even influences to active termination the peripheral limits of an ulcer in which granulation has long entirely ceased.

The utility of skin-grafting has, in my observation, been in no instances more demonstratively shown than in cases of extensive denudation caused by destruction of skin, as in burns, and of loss of large areas of integument from traumatic injuries. In the case of a man whose back was extensively charred at a lime-kiln, while lying under the toxic influence of its emanations, the sloughing integument having left an immense area of ulceration over his dorsal and lumbar regions, the successful engrafting of numerous minute pieces of skin healed the vast ulcer with astonishing rapidity. In an instance of the entire loss of the skin of a leg, caused by deeply burning with coal oil, which had filled a shoe and saturated a stocking, the healing process was by the same procedure rendered as surprising and satisfactory.

It seems now probable that amputation, which, as a final resource, is by surgical authority justified in certain cases of extensive ulcers of the leg which all expedients have failed to heal, may be substituted by the simple device of skin-grafting.

All of the conditions essential to successful skin-grafting I have not, after extended observation, fully determined. The most favorable condition for the development of the grafts is certainly that of healthy, active granulation of an ulcer; and the more nearly this state is approached, the greater, as a rule, will be the success. The grafts, however, occasionally fail, for incomprehensible reasons, on surfaces of perfectly healthy granulation; and yet I have repeatedly succeeded in developing such healing centres in the midst of ulcers of general unhealthy aspect, even where ulceration was actively

spreading at the circumference. An instance of effective grafting on an unhealthy surface was once illustrated to me on one of a number of chronic syphilitic ulcers of rupial character located on the arm.

As an illustration of ineffectual grafting on a healthy surface of granulation, I recall the case of a young woman, admitted to the Pennsylvania Hospital, whose almost entire scalp was torn off by her hair being caught in the cog-wheels of the machinery of a factory, leaving an exposed surface of pericranium. I failed, after many attempts, in inducing grafts to retain their vitality. The granulating surface was in a healthy condition, and grafts, more than one hundred in number, from the patient's own skin and from that of several other individuals, were repeatedly tried without success. The experience I have had since that case was under my control would now induce me to try grafts taken from *another scalp*, as it seems that grafts from similar localities, as from one eyelid to a loss of integument or a plastic operation on a corresponding part, retain their vitality almost certainly. I may here, however, remark that the transplantation of hair-follicles has, I believe, in all experience, uniformly failed.

The influence of the grafts in vitalizing the surface of chronic ulcers may be demonstrated by consecutively repeating the transplantations as the process of granulation becomes sluggish, each grafting exciting a renewed healing impulse, and preventing the tendency to relapse into indolence until the entire surface is cicatrized. I am inclined to think that with this kind of persevering repetition there must be few chronic ulcers, whatever may be their condition or location, which cannot be healed.

One of the beneficial claims for skin-grafting is with reference to the avoidance of the eventual contraction which disfigures, deforms, and impairs motion after extensive loss of integument. Observation seems to show that where cutification is rapid from a number of skin-forming centres the resulting cicatrix is less violently contractile in its tendency.

Some operators have experienced disappointment in the grafting procedure, on account of the liability of the newly-healed surfaces to a rapidly destructive ulceration under slight disturbing influences. I have seen a number of illustrations of the susceptible and readily-perishable nature of the rapidly-healed spaces. In one case of extensive and rapidly-healed surface, I saw the whole delicate cicatrix seem to dissolve and disappear almost within the period of a single day, during the existence of a general feverish exacerbation violently affecting the patient.

The delicacy and susceptibility of the newly-formed tissue are merely incidental to its neoplastic character; and the practical lesson to be impressed is the careful avoidance of local and constitutional influences that may destroy it.

In regard to the previous preparation of the surface of a chronic ulcer for the reception of skin-grafts, the more nearly it is brought to a normally

granulating condition the more likely is success to follow; nevertheless, much reliance may alone be placed on the vivifying influence of the simple presence of the grafts on indolent surfaces.

For successful skin-grafting, it is simply essential that a minute portion of skin be removed from a sound part of the body of the patient, or from another individual, and placed on an ulcerated surface. It is customary to take the pieces to be transplanted from the patient's own skin; and I have generally chosen locations where the derma is thin, and not densely covered with cuticle, as on most of the front of the body, and, as a choice, from the inner surfaces of the arms and thighs. Grafts from the integument of other individuals develop as readily, and I have frequently practised removing them from limbs amputated for traumatic injuries, with apparently equal success. To avoid the possibility of conveying some form of specific infection by the process, it is certainly, as a rule, most advisable to transplant only from the patient's own skin.

A graft of skin should merely consist of the simple structures of cuticle and derma, and should avoid the underlying fatty and connective tissues. That even the whole thickness of the derma is not essential, is demonstrated by the fact that successful grafting has been effected by using mere scrapings of the cuticle, in which are contained some cells of the superficial or papillary layer of the derma; but the practice is uncertain, and has not practical merit. The thickness of the true skin on the front of the body, it should be borne in mind, does not average more than from a quarter to half a line, and this depth should never be exceeded in the removing of grafts.

The operation of removing the portions of skin for grafting may be done by a knife or scissors, cutting off minute particles of the size to be used immediately in transplanting; or by taking a larger piece which is to be afterwards subdivided. I formerly practised the removal of skin for grafting by seizing the skin with delicate forceps and snipping off a piece with small scissors, using the fixation forceps and curved scissors of ophthalmic practice. The fragment removed was then spread on any convenient surface, as on the flat extremity of the

handle of a scalpel, and subdivided into pieces varying in size from that of a grain of canary-seed to that of a grain of rice.

To facilitate the detaching of pieces of skin on the above plan, Mr. Bryant, of Guy's Hospital, London, has devised an instrument in which the forceps and scissors are combined, and which accomplishes the object at a single movement.

During the last year I have adopted a method, first suggested to me by Dr. C. H. Thomas, of this city, which, for simplicity, convenience, painlessness, and effectiveness, may well displace all others.

It consists, as seen in the cut, in merely penetrating the *cuticle* with a very delicate sewing-needle, elevating a small point, and shaving off the minute elevation of cuticle and upper stratum of derma with a very sharp knife. The same may be accomplished, but hardly in so perfect and painless a manner, by using fine scissors for the excision of the portion transfixed.

The operation, if properly performed, should be free from really painful sensation, and patients never object to its most frequent repetition. I have frequently done it without more than a tint of discoloration from blood, and blood need never actually flow from the very minute wound.

The graft is then immediately pushed from the point of the needle, and placed on the surface of the ulcer, the only care being to lay it with its epidermic surface upward. The graft need not be inserted into the granulating surface by making a wound for its reception, as has been advised and practised, for such puncture allows a flow of blood that may elevate the graft from contact with the granulations.

As simple adhesion of the graft is all that is desirable, I have sometimes, with large and actively secreting surfaces, allowed them to be exposed to the desiccating influence of the atmosphere, so that the secretion may become viscid and hold the transplanted particles securely in position. To facilitate the same object of fixation after the grafts are deposited, I have occasionally allowed the ulcerated surface to remain uncovered until they became well agglutinated to it.

All active medication to the ulcer should be avoided, and the surface of ulceration be simply covered with a light dressing, for protection from disturbing influences. For this purpose the ulcer may be covered with a piece of muslin, saturated with oil or covered with cerate, or it may be merely protected with the waxed tissue-paper, such

as is extensively used for general purposes of a dressing in the Pennsylvania Hospital.

On most ulcers the dressing need not be removed for two or three days after the operation; but when secretion is profuse, the ulcer may be washed daily, by allowing a stream of water to flow over it, carefully avoiding the wiping of the surface with sponges or cloths, which may disturb the grafts.

One of the earliest changes noticeable in the graft, after the first few days, is the detachment of its cuticle, which may occasionally be seen floating in the secretions of the ulcer, or it may be detached by a slight touch, leaving the true germinating material fixed in position. The graft, as it commences development as a germinal centre, becomes so blended and identified with the granulations as to be for a time almost lost sight of, its reappearance becoming evident in a bluish or lilac-tinted pellicle, which indicates the progress of cutification.

In regard to the size of grafts for transplanting, I have, in several instances, grafted by removing from recently amputated limbs pieces of skin measuring one-third or one-fourth of an inch square; but such large pieces are very likely to fail in retaining their vitality, and I have had much more satisfactory success with quite small grafts; and, for reasons already stated, this latter practice is certainly the best.

The number and position of the grafts will vary in accordance with the size of the ulcerated surface; and in large ulcers they may be distributed at short intervals, both centrally and near the periphery. Those near the circumference will stretch their granulations outward and stimulate the borders of the ulcer to activity; and, with regard to the advantage of centrally-located grafts, it will be well to remember their importance with reference to the difficulty often experienced in eventually healing the last of a chronic ulcer. A large ulcer, on which successful grafting has been performed, will soon present islets, from which cicatrization progresses in directions of the nearest healing-points, until all are joined by an interlacement of newly-formed tissue.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS, M.D.

Reported by J. B. ROBERTS, M.D.

SPONTANEOUS ANEURISM OF ONE OF THE BRANCHES OF THE DORSALIS PEDIS.

DAVID T., a colored man, aged 59 years, presents himself at the clinic with a tumor about the size of a small bird's egg, situated upon the external aspect of the dorsum of the left foot, and which he first observed four months ago. The tumor shows no discoloration, is without adhesions to the surrounding tissues, and appears to be connected with the thecæ of the tendons going to the toes; in fact, it resembles very much the ganglion, or cystic tumor, so often found in connection with the extensor tendons of the hand.

Upon more critical examination, however, there is perceived distinct pulsation, which is rather too evident and too diffused to be caused by transmission of im-

pulse from an artery lying immediately below the tumor, although I have seen a number of instances where a ganglion situated over the radial artery has had the pulsation of that vessel imparted to it, so that it was at first mistaken for an aneurism. In this case, however, I am nevertheless inclined to believe that the tumor is not a cyst of the sheath of the tendons, but an aneurism, involving one of the branches of the dorsal artery of the foot; for the *dorsalis pedis* itself cannot be involved, because the swelling is external to it; and hence one of its tarsal branches must be dilated.

Spontaneous aneurism of the arteries of the leg and foot is very unusual, and there is probably no case recorded where such an affection has been observed connected with the *dorsalis pedis*; though a number of instances of traumatic aneurism in this situation, particularly after venesection, have been reported.

An exploring-needle is introduced into the tumor; and the withdrawal of the instrument being followed by an escape of blood seems to confirm the diagnosis of aneurism.

It is necessary to undertake some form of operation for the cure of the affection, if it be an aneurism, because, should the patient meet with an accident causing rupture of the sac, he might bleed to death before surgical assistance could be procured. Pressure will, accordingly, be made by an assistant upon the femoral artery to arrest the current of blood, and then the tumor will be laid open with the knife; which is readily effected by carefully dividing, upon a grooved director, the overlying tissues until the tumor has been reached. The amount of blood which escapes from the incision in the tumor as soon as compression upon the femoral artery is relaxed reveals conclusively the true nature of the case, and shows the tumor to be aneurismal.

It seems impossible to separate the sac and trace out the artery by which it is supplied, and hence it becomes necessary to ligate the anterior tibial, which is accomplished by extending the incision upward, and passing a ligature around the vessel just above the ankle, where it lies between the tendons of the *extensor longus digitorum* and *extensor proprius pollicis* muscles. There is still copious hemorrhage proceeding from the recurrent circulation, which is dependent upon the perforating branches of the plantar arteries; and from the great number of ligatures required to arrest the bleeding, it would appear that the tumor has somewhat the character of an aneurism by anastomosis.

The hemorrhage, after a good deal of difficulty, has finally been controlled, and the wound will now be covered with cotton saturated with Monsel's solution, and the patient carefully watched lest hemorrhage again supervene, necessitating some further operative procedure.

This man, who was before the class a week ago, did well until to-day, when copious secondary hemorrhage occurred, necessitating the temporary introduction of three pins to arrest the bleeding.

With the assistance of Professor Pancoast I shall now try the effect of ligating the anterior tibial some distance above the point of the old ligature, which came away this morning; and then, if hemorrhage continues from the wound after these pins have been removed, it will be proper to cut down upon the part, and, making a large flap, endeavor to control the bleeding by tying the small vessels. Should this be found impossible, it will be necessary to amputate the foot, for it would not be advisable to attempt ligation of the femoral artery, since the vessels are so atheromatous and fragile that the ligature would probably separate prematurely, and the patient die from immense secondary hemorrhage.

By means of a curvilinear incision here at the lower

third of the leg, I come upon the artery about three inches above the joint, and without much difficulty pass the aneurismal needle under it, and tighten the ligature. Upon removing the pins introduced this morning, but upon which I was afraid to depend, the hemorrhage does not recur, and therefore I shall not do anything further to-day, but have the man well watched, that the occurrence of bleeding may be immediately recognized.

I have this morning, gentlemen, to announce the death of our patient with aneurism of the foot, who was before the class two weeks ago, when, as you remember, I applied a second ligature to the anterior tibial artery. This ligature was removed on the ninth day, and the man seemed to be doing quite well, with the exception that he had a severe chill on the eighth day, and that there was considerable sloughing of the wounds. He, however, died last night, and the post-mortem examination shows both wounds filled by granulations, and one of them with a slough; the anterior tibial, as well as the femoral arteries, ossified, pus in the joint, and the heart fatty, with slightly atheromatous valves. As the man had been very stupid for some time, I thought death might have been the result of embolism of the cerebral arteries; but the autopsy gave no evidence of clots in the brain, and I therefore attribute his death to pyæmia.

EXCISION OF ONE-HALF OF THE HARD PALATE FOR THE REMOVAL OF AN ANGEIOMA.

Mary McK., 6 years of age, from the State of Wisconsin, was attacked about eighteen months ago with frequent hemorrhages from the mouth, proceeding from the gum between the molar teeth on the left side of the upper jaw, and which were at times only arrested by the application of styptics.

About a year ago an operation was performed, which proved ineffectual, for, within the past few months, bleeding has recommenced and the tumor has been gradually increasing in size, accompanied with pain in the cheek and ear, but without any recurrence of nasal hemorrhage.

This tumor is an angioma, resembling the nævus that occurs in the skin, but is not an aneurism by anastomosis, which is occasionally developed in connection with the upper jaw and in the maxillary sinus, because it does not exhibit pulsation synchronous with the beat of the heart. It is impossible to determine whether or not this growth involves the antrum, for, although there is apparently no complication of the nasal cavity, the tumor may entirely fill the antrum of Highmore and be encroaching upon the nares.

An incision is made from the commissure of the lips, extending about three inches outwards towards the ear, in such a manner, however, as to preclude the occurrence of injury to the facial nerve and the duct of the parotid gland. This external wound is rendered necessary by the size of the tumor, the removal of which through the mouth would be impracticable. The facial artery, which has been divided, is secured by a ligature, and the flap dissected back to give sufficient room for the performance of whatever operative procedure may be required to extirpate thoroughly the morbid growth.

This disease appears to involve the palatine process both of the superior maxillary and the palate-bone on the left side, but without having invaded the antrum of Highmore; and therefore the excision of half of the roof of the mouth will be necessary to effect complete removal of the diseased structures. In order to accomplish this, the bone-forceps are introduced—after the incisor teeth have been extracted—into the anterior nares and the mouth, to cut through the alveolar process and the hard palate near the median line, and,

when this has been effected, are again applied so as to separate the palatine process from the body of the maxillary bone.

There is considerable hemorrhage, resulting from the division of the posterior palatine artery and the numerous smaller vessels in this situation, which will be controlled by applying styptics and plugging the antrum with cotton saturated with subsulphate of iron. If bleeding from the posterior palatine artery persists, it can be arrested by the application of the actual cautery; for the ligation of the vessel, situated, as it is, so far back in the mouth, would be impossible.

Here is the little girl from whom, two weeks ago, was removed half of the roof of the mouth on account of a tumor which was at intervals the seat of hemorrhage. After the bleeding from the wound was controlled, the edges of the incision were approximated by sutures and adhesive strips, and the patient placed upon iron, quinine, and stimulants. She has convalesced quite rapidly, and purposes going back to her home in a few days, though it would be better if she were able to remain here some time longer, so that should the growth show any tendency to reappear, which is not at all improbable, the actual cautery could be employed to arrest it.

EPITHELIOMA OF THE RECTUM.

G. M., 57 years of age, has suffered for about two years with an obstinate diarrhœa accompanied with intense pain and tenesmus, and occasionally with copious hemorrhage from the bowels; and latterly the fæces, when passed, have not exceeded in diameter the size of an ordinary lead-pencil.

The symptoms presented by the patient point towards the existence of a carcinomatous stricture of the rectum; but in order to establish the diagnosis it is necessary to make a digital examination of the bowel, which is readily done by inserting the finger, previously oiled, through the anus by a rotatory motion. At the distance of two and a quarter inches from the verge of the anus a growth is distinctly felt, forming an irregular ring around the entire circumference of the bowel, leaving only a small aperture in the centre. This is, therefore, a case of epithelioma, or scirrhus, as it was formerly called, of the rectum, which has caused by its growth an annular stricture, through which the fecal matter escapes with great difficulty.

This is the most frequent form of cancer occurring in the ano-rectal region, for the other varieties of carcinoma have been very rarely seen in this situation. The disease is usually met with in elderly subjects, but sometimes the patient suffering with this malignant affection has not attained even adult age.

In its advanced stages the disease presents characteristic symptoms, being attended by sharp, lancinating pain, difficult defecation,—though the calls to evacuate the bowels are exceedingly frequent,—and the passage of mucus, blood, and pus from the rectum. Frequency of micturition occurs from reflected irritation of the bladder; the distention of the bowels with fæces and gas gives rise to colicky pains; the fæces, when passed, are flattened in form and of small diameter, and the countenance of the patient gradually assumes the carcinomatous cachexia.

The treatment of carcinoma of the rectum is of necessity only palliative. Billroth, of Vienna, and several other surgeons, have excised the rectum for the removal of the malignant growth; but the operation is attended with profuse hemorrhage, and seems a barbarous and unjustifiable procedure, since there is so little probability of any ultimate advantage accruing from its performance.

Great relief of the symptoms can often be obtained

for a considerable length of time by breaking down the stricture with the finger, as I do in this case, or by the forcible insertion of a bougie. The finger is the safer method of effecting this object, because the operator has more control over the amount of pressure exerted, and is less apt to cause rupture of the bowel, which unfortunate complication would necessarily be followed by peritonitis and almost certain death of the patient. The only other treatment is the employment of tonics and anodynes, together with the administration of soothing and detergent enemata, in order to render the condition of the patient as comfortable as possible.

TRANSLATIONS.

PSEUDO-MUSCULAR HYPERTROPHY (Dr. Ludwig Schlesinger, *Wiener Med. Presse*).—The first publications relative to this malady appeared in 1838, in Naples, containing the histories of two cases of a peculiar disease of the muscular system, in which there was a diminution of the power of the muscles, accompanied by an increase in their volume.

From time to time narratives of similar cases appeared in the journals; but no one attempted to give any theory relative to the origin of the disease until 1861, when Duchenne called more particular attention to it, and referred it to some cerebral affection. As he had no opportunity of observing the disease, except in children, he suggested the name "*paraplégie hypertrophique de l'enfance de cause cérébrale*" for it. To him belongs the credit of first calling the attention of the medical world to it, and since that time about one hundred cases have been placed on record. In most of these cases, in addition to records of the clinical phenomena observed, microscopic examinations of small pieces of muscular tissue were made, and in some cases records of the post-mortem appearances were kept; but, owing to the striking discrepancies in the results of these observations, up to the present day no unanimity in regard to the exact pathology of this disease has been reached. While some observers, relying upon the conditions noticed at autopsies, being struck by the wide-spread changes both in the peripheral nerve-trunks as well as in the spinal cord itself, support the theory that the origin of the disease is to be found in pathological nerve-changes, others of equal eminence do not countenance this view. The idea of a cerebral origin has been given up by all, even by its originator, Duchenne. A like difference of opinion exists in regard to the condition of the muscles, as to whether the atrophy of the muscular fibres is the first factor in the pathological change, and the growth of the interstitial tissues is consequent upon it, or whether the latter condition should be looked upon as the cause of the former: not long ago, Friedrich, of Heidelberg, published a valuable monograph on "*True and False Muscular Hypertrophy*," in which he endeavored to prove the identity of progressive muscular atrophy with pseudo-hypertrophy, regarding both affections as results of chronic myositis, one being distinguished from the other only by unimportant modifications of the results of a hyperplasia of the interstitial connective tissue.

Upon examining the numerous cases reported under various names, it is found that they, with but few exceptions, present a common type.

In most cases the process begins in the earliest youth. In but few is it found to originate at the time of puberty. There is frequently found a hereditary predisposition, and it but rarely commences in adult life. The children affected are, for the most part, those who have been weak from their birth and have developed slowly. The parents notice that at the age when children are usually

able to walk, they have not even made attempts at progression; and when later, in their fourth or fifth year, they do begin to walk, they fall readily, and their gait is unsteady. Soon there is noticed increase in the volume of some of the muscles, usually first in those of the calf, and this is accompanied by contraction of the tendo Achillis, from which results a drawing-up of the heel. Gradually the muscles of the thigh and loins, sometimes also those of the upper extremities, increase in size, while at the same time other muscles of the trunk or arms become atrophied. The loss of power of the muscles stands in marked contrast to their increase in volume. In a short time curvations of the spine develop, and, as the disease progresses, the power of standing and of locomotion is lost, the patient is no longer able to make the simplest movement, he cannot turn himself in bed; and he remains in this condition until death occurs, either from paralysis of the diaphragm or from some intercurrent pulmonary trouble.

Microscopic examination in most of these cases reveals simple atrophy of the muscular fibres, with an enormous increase of the interstitial, fatty, and connective tissue. In a few of these cases it is found that the muscular fibres have almost entirely vanished, and have been substituted by fatty tissue. The wide-spread degeneration noticed in the nervous system has been previously mentioned. This type of the disease, as related above, has been noticed but rarely in adults,—only four or five times.

Auerbach and Berger, in Breslau, have recently published notes of four cases which are markedly distinguished from the usual type both in their clinical history and in their structural lesions. In all four of these cases the disease was consequent upon an injury, and affected the muscles of but one limb; in one case the muscular tissue of the right arm alone being involved, in the other three that of the left leg. The functional changes were by no means so marked as in the typical cases; in place of a total loss of the power of motion, only a diminution was noticed. The microscope revealed in these cases a true hypertrophy of the muscular fibres, but the excessive growth of the interstitial tissue was wanting.

These two observers seem to look upon these cases as belonging to the category described above, and regard them as cases in which a false hypertrophy may develop through the disappearance of the hypertrophied muscular tissue and the growth of the interstitial tissues.

Schlesinger recently had the opportunity of observing a patient who had been sent to the hospital on account of some mental disease, but in whom he also found some hypertrophy of the muscles of the left side. By a microscopic examination he found the muscular tissues of this man much diseased, and he thinks himself justified in concluding that the disease in this case started in the muscular fibres, and that the interstitial tissues were secondarily involved. Whether the process was simply an inflammatory one of the muscle, or whether there was primarily some alteration of the nervous system, cannot be decided; but he is inclined to the opinion that the disease was a chronic inflammatory process of the muscular substance. The results of his observations lead him to a different conclusion from that maintained by Auerbach. From the circumstances that he failed to find any muscular fibres which were hypertrophied, and that he did find evidences of disease in fibres of normal size, Schlesinger concludes that in the case which came under his notice there was no stage of true hypertrophy. W. A.

DR. J. H. SAUNDERS reports (*Canada Lancet*, March 2) a case of recovery without vomiting in a man who had swallowed an ounce of chloroform.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 21, 1874.

EDITORIAL.

THE ANNUAL OVERFLOW.

NEXT week the profession will be more numerous by some hundreds than it was before the colleges flung open their doors and let the anxious crowds come out. The profession grows in numbers by the annual increment, but does it grow in power? We fear not. As the addition of new links of imperfect workmanship lengthens but weakens a chain, so, it seems to us, does the yearly growth increase but weaken the profession. It appears to be in the first place indisputable that the influence of the profession, so far from growing stronger, really lessens with age. To-day, in circles where formerly the physician was held in high esteem, he is looked upon as a puzzle, a problem, a *lusus naturæ*, a something removed from the common humanity; and in other circles of power regular medicine, quackery, imposture, and ignorance are jumbled into a mass, and the profession is weighed by the general average.

The reasons of the declension of physicians in public esteem are no doubt manifold; but the roots of all these causes seem to us to take life upon Commencement day. In the yearly outpouring of semi-educated men is furnished the leaven that is leavening the whole lump.

We are not of those who believe there are any real differences in the schools. It is in our judgment "six of one and half a dozen of the others." An incident which came under our notice will serve as an illustration of the evil, and is not an

unfair example of the workings of the present system of education. Mr. — was a cooper by trade; he was an excellent workman. Merrily from early dawn to dusky eve he drove the hoops home on the great molasses-hogsheads, or deftly fitted the staves of the whisky-casks. By thrift and toil he prospered and became a master-cooper, and then, by shrewdly making his bargains and industriously working with his men, he acquired sufficient property to render him independent of his week's or month's labor. But times grew dull: molasses-hogsheads were not wanted, whisky-casks were a drug, even flour-barrels were at a discount. One day, as our hero was walking along the streets, pondering with sunken head upon this sad state of affairs, he heard a bell ring, and, looking up, he saw before him a large building, and on inquiring was told that it was a medical college, and that the bell had been rung not for an auction but for lectures. A brilliant idea seized him, thrilled him to the marrow, and almost took his breath. He would become a doctor. Wasn't it better to be Dr. Smith than Cooper Smith among his neighbors? Wasn't it easier to feel pulses than to wield the adze and the mallet? So said, so done. In two years the garments of the cooper were shaken off, the pompous roll of the Latin had awakened its echoes in the cooper's soul, and the robes of medicine had been put on. We do not wish to be misunderstood, or in any way to sneer at honest labor or at small beginnings. A man may rise from the peasant's hut to the sublimest height of intellectual power and deserved fame; but he rises only by steady, persistent efforts,—efforts whose sources are the in-born instincts of his soul, and not the offspring of exoteric circumstances. Our cooper was a cooper still; cooper in intellect, heart, and soul, but doctor in law and doctor by authority. He had earned his degree by attending lectures and paying his fees; by dint of coaching by young physicians who had brought their art to such perfection that they could tell almost to a certainty the questions which would be asked in the green-room,—by dint of such coaching he had been able to resist the pin-scratches officially made to test the candidate's knowledge, and he was by right and by law a doctor. His fitness may be gauged by the fact that shortly after his examination he came in great glee to one of his coaches, stating that some unfortunate wretch suffering from chills had come to him for treatment; that he wanted to give quinine, and would the doctor please write a prescription, that he might copy it?

American practitioners of the better class are

equal, we firmly believe, as practitioners, to any in the world; but many of them acquire their knowledge and skill *after* graduation, and many of them, though skilful practitioners, fail entirely in those public duties by the manner of whose performance the profession is judged: not educated during their student life in hygienic medicine or in medical jurisprudence, and having little call for such knowledge afterwards, too often a judicial investigation or a public discussion of a hygienic problem is simply a public disgrace of the profession. When coroners' physicians in our largest cities make such judicial examinations that their testimony is ruled out of court, when the absence of contention and strife between doctors is the rare exception in court proceedings, how can the public judge otherwise than they do? More than this, owing to our system of manufacturing doctors, great numbers of the ignorant enter the profession; many of them finally to go back to their cooper-shops, some of them to achieve practical success and to build up remunerative practices. We doubt not that some of our readers will remember a doctor of this town who accumulated a competency, although "stumick" was the key-note of the English of his prescriptions. The colleges as at present organized are in very truth the enemies of the profession. The colleges, we say,—not the faculties: we are willing to grant that they do their duties conscientiously.

We know that many of the professors see with the clearness of propinquity the sources of evil and sadly acknowledge the gravity of the trouble. Yet they are powerless to alter or reform: the instruments of an organization, they are responsible only for the method in which they perform their assigned duties. The demand made upon them by some of the profession that they change the system has seemed to us ludicrously unjust, if not absolutely impudent. This may appear strange to some; but, as our columns are crowded, we must leave the development of our reasons for another issue.

CORRESPONDENCE.

THE BIDDENDEN MAIDS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

THOUGH these ladies may not have figured in the pages of "scientific" journals, they have long been famous in print, as well as in local tradition. I find at least three accounts of them in books on my library shelves: in Chambers's "Book of Days," vol. i. p. 427; in Brande's "Popular Antiquities," vol. i. p. 166; and in Timbs's "Something for Everybody" (Lon-

don, 1861), p. 54. All these authorities quote Hasted's "History of Kent" (published in 1790), in which the story is shown to be a "vulgar tradition," without historical foundation. Hasted says that "the truth seems to be that it [the bequest] was the gift of two maidens of the name of Preston; and that the print of the women on the cakes has only taken place within these fifty years, and was made to represent two widows, as the general objects of a charitable benefaction." In the year 1656 the Rev. W. Horner, rector of the parish, claimed the lands as a part of his glebe, but failed to get them; in the pleadings preserved in the church, the names of the ladies are said not to be known.

It is worth mentioning, by the by, that, according to the tradition, the "maids" were connected both at the shoulders and the hips, having only one pair of arms, but two pairs of legs.

The costume of the figures on the cakes is of the time of Mary: "open bodices, laced, Vandyke ruffs, and sleeves slashed at the shoulders," with the head-dress of that period.

CAMBRIDGE, MASS., February 23, 1874.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, FEBRUARY 18, 1874.

THE PRESIDENT, DR. JOHN SWINBURNE, in the chair.

A CASE OF NEPHRITIS.

DR. R. H. SABINE reported a case of nephritis. Mrs. V., æt. 29, of tuberculous tendencies, and the mother of five children, being very near the end of her sixth pregnancy, through the course of which she had been unusually well, accidentally struck herself on the knee; she was instantly taken with pains in the abdomen, which soon went to the back; they were continuous, but more severe at times, and she supposed them to be labor-pains.

A grain and a half of opium were given, and chloroform by inhalation, the opium being repeated in two hours. After this the pain took on more the character of that of labor; the os dilated fully in about five hours, and the fœtus, weighing about three pounds, was delivered by forceps. What were supposed to be after-pains were very severe, and opium was given again. Twenty hours after delivery she was found much exhausted. She had passed no water, and on using the catheter the bladder was found empty.

Next day she showed a puffy look about the eyes, a pallor of the face, and symptoms of uræmic poisoning. There was still suppression of urine. Cathartics and diuretics were administered; the former only operating. She finally passed into a condition of stupor, and died at the end of the third day.

Post-mortem.—The bladder was found empty and dry.

The kidneys were inflamed and enlarged, one of them weighing ten ounces. The uterus was contracted, and contained a dark offensive discharge.

The President inquired in how short a time death had been known to occur from congestion of the kidneys and suppression of urine. He had never known it to occur in less than three days. This is interesting in a

medico-legal point of view; a prominent physician had asserted on the witness-stand that a person going to bed at night entirely well may die before morning of uræmic poisoning. When such men make so strong an assertion, the matter ought to be investigated.

Dr. J. L. BABCOCK remarked that this depended on the amount of urea in the circulation. He gave the details of a case in which during four days not more than half a pint of urine was passed, in which the symptoms characterizing congestion of the kidneys were present; under salines and cups with hot fomentations to the back the patient improved and recovered.

Dr. F. C. CURTIS spoke concerning the part taken by the blow on the knee in the etiology of the affection of the kidneys in Dr. Sabine's case. He alluded to a case which he reported to the Society in May last (see *Medical Times*, vol. iii. p. 566), in which a patient in sound health met with a fall, hurting his head and back, followed immediately by symptoms of acute nephritis, resulting in death within three months. Dr. Brown-Séquard had written on this subject of external injuries producing disease of internal organs, by nervous sympathy probably. In many cases this point may be an important one.

Dr. C. D. MOSCHER said it was pertinent to inquire as to the effect of the opium given in this case. It is well always to make sure of the condition of the kidneys in the lying-in state before administering it, although it is generally given very indiscriminately. Opium, as well as chloroform and all anodynes, seems to aggravate an existing disease of the kidneys, and the continued use of anodynes before delivery may often bring it on.

Dr. JOSEPH LEWI remarked that the tuberculous tendency, and in addition the pregnant condition of the patient, as reported by Dr. Sabine, would tend to hasten her death. He had observed in these cases a small quick pulse, a characteristic sweat, and a smell of urine about the patient.

He had never seen bad effects from opiates in either acute or chronic Bright's disease, when given with discretion—*i.e.*, symptomatically—by a careful physician.

Dr. VANDERVEER said that he had given opium in some cases of albuminuria with pleasant results, and in others with the opposite. In one case of chronic albuminuria convulsions came on after the exhibition of opium, and in another he had seen forty drops of laudanum by enema produce coma and death. As to the length of time a patient lives with suppression of urine, he had a patient in May, 1866, of dissipated habits, who was sick three days and recovered; recently he had another attack, which lasted five days, when he died. Although he suffered great pain, but little opium was given.

The President said that a distinction should be made between acute and chronic inflammation of the kidneys. In the former there is no albumen at first in the urine, and in these opium is badly borne; in the latter there is albumen, and in it opium is better borne, but still not well. He had never seen recovery from a very severe attack of acute nephritis.

PUERPERAL INSANITY.

Dr. JOHN B. STONEHOUSE, JR., said that a consideration of puerperal insanity is interesting from the rarity of its occurrence, the absence or obscurity of its prominent symptoms, the difficulty of treatment, the uncertainty and often fearful termination of the disease. According to the strict significance of the term puerperal insanity, these remarks could refer only to those cases which occur during or within a few days or weeks after delivery; but by usage it has come to include instances of mental derangement originating during the periods of utero-gestation, parturition, and lactation. The late Dr.

Skac, in the Morisonian Lectures for 1873, published in the *London Journal of Mental Science* for October, 1873, abandons the term, and divides it into "puerperal insanity," insanity of lactation, and insanity of pregnancy. While the term is decidedly an inappropriate one, it is necessary to treat the cases together, because of the intimate connection of these three physiological stages and the almost inseparable connection of their etiology and pathology.

The most usual division of the subject is according to the periods of pregnancy, labor and its consecutive state, and lactation; another division is ephemeral insanity, melancholia, and mania. The latter classification is faulty, inasmuch as it does not take cognizance of the peculiar circumstances under which the disease is developed, and dependent upon which are the treatment and prognosis. We will then consider insanity and pregnancy, puerperal insanity, and insanity of lactation.

The period of pregnancy is understood to extend from conception to delivery; the period of labor to the end of the second month; the period of lactation from the second month after delivery.

Of the fifteen cases of puerperal insanity on which I found my remarks, thirteen were married women; ten were between the ages of twenty and forty; three were under twenty, and two had passed forty; eight were primipara, four cases occurred during the second pregnancy, one during the third, one the fifth, and one the eighth. The youngest was eighteen, the eldest forty-seven years of age. In four cases there were histories of heredity; the insanity in all cases having occurred on the maternal side. In five cases hereditary neuroses other than insanity were found; and in the remaining six no heredity could be traced. In six cases the patient had suffered from nervous disease previous to the attack, and in one case an attack of chorea ceased as the mental symptoms came on.

Two cases proved fatal: one from dysentery, and the other from maniacal exhaustion; four cases are at present in institutions, and considered incurable; nine recovered. Of the four incurable cases, one is in a condition of dementia, and the others are classed as suffering from chronic mania.

Of the fifteen cases, six occurred during pregnancy, three during labor, and the remaining six during lactation.

Now allow me briefly to detail the cases which appear to me to be representative of the several varieties, course, and termination.

Case I.—H. J. P., æt. 30, second pregnancy; married five years. Patient exhibited symptoms of mental aberration during the fourth month of pregnancy; fears of poverty and death, with perverted appetite,—craving raw meat, etc. Symptoms developed rapidly, and from the fifth month to the time of labor patient continued in a condition of extreme melancholia, without suicidal propensities. During labor, however, she exhibited considerable interest, and immediately took the child to breast, and to the close of lactation showed no other symptoms of mental aberration. The patient has suffered several times from very severe hemiplegia. Parents and collaterals free from any nervous taint, whilst they are decidedly phthisical. This patient entered an institution during the fifth month of her pregnancy, and was discharged one month afterwards.

Case II.—G. S., German, æt. 23; married one year; primipara; during an instrumental delivery she became violently excited, and charged her husband with attempts to murder her by means of the forceps. Tried to choke the physician while applying the bandage. It became necessary to use the camisole, for the safety of the household.

Under medical treatment she quickly recovered her former mental condition, having been deranged and

under restraint about two weeks. She did not nurse her child. Is again pregnant. No heredity could be traced. No nervous affections in her previous history.

Case III.—D. H., æt. 39; married two years; first pregnancy; during utero-gestation patient was suspicious and apparently very religious. Was not considered by her relatives to be in sound mind. Labor not very difficult, nor marked by any special mental symptoms. During lactation, patient complained of headache in frontal region. Anæsthesia—partial—was noticeable for a few days at several periods. Mental symptoms increased in intensity. Several attempts at suicide occurred, and in the fourth week after delivery, by the advice of the family physician, she was removed to an asylum. A year has elapsed, and the patient is in a state of profound dementia. During the past summer she suffered from a severe dysentery, and became extremely debilitated; had bed-sores. Following this was an obstinate constipation, with atony of the bladder.

Late intelligence gives no hope of recovery.

Case IV.—L. F., of German descent, æt. 18; unmarried; first pregnancy; patient was from a wealthy family, eldest of eight children; three have suffered from epilepsy, two died in infancy from convulsions. She was first attacked when ten years of age. Her mother and several other relatives on the mother's side also give histories of nervous heredity, an aunt and a brother having died at an asylum, of epileptic insanity. The patient, being of weak mind and morals, fell an easy prey to a man much her senior. During pregnancy she exhibited no unusual mental symptoms. During labor, however, she became wild and incoherent in her talk. In the course of a week she was dangerous to herself and her attendants, requiring the use of the camisole continually. The fauces became extremely congested and swollen from the violent and constant screaming. Insomnia was almost unmanageable. Only while under the effects of the most powerful soporifics did she rest from her delirium. Forty-five grs. of chloral and one drachm of a saturated tincture of hyoscyamus would scarcely produce rest for half an hour.

Beef-tea, whisky-punch, and medicine were given either by stomach-pump or by enema, according to the excitement of the patient. Hypodermic injections of morphia, even to the extent of one-half grain, produced no effect, although repeated within an hour. On the thirteenth day after labor she died from exhaustion.

Case V.—M. E. P., æt. 27; married; primipara; family strongly nervous during pregnancy; premature labor was threatened twice. Labor was without any special unfavorable symptoms. In the fifth week of lactation she first exhibited signs of mental aberration; refused food; could not be induced to utter a word; fæces and urine were passed apparently without her knowledge. She sat in her chair with her hands upon her knees, her eyes cast upwards, and her mouth open. It became necessary to force alimentation and medication. Extreme insomnia and debility also further complicated the case. Under treatment she became steadily better until the third month of lactation, when she was discharged cured.

A few words as to the etiology of these affections. In Westminster and Queen Charlotte's, two large lying-in hospitals of London, among 5500 women confined, only twenty were attacked with the disease during their residence in these institutions, and in others the proportion has been small. These facts, however, do not show the whole number attacked, as the time spent in lying-in hospitals after delivery is usually very short, and women attacked with insanity during pregnancy are seldom if ever delivered at an institution.

Dr. Gundry, from collected cases, gives 1434 cases of puerperal insanity in 16,109 cases admitted to insane asylums.

Among the causes, hereditary predisposition appears to be the most important. This heredity, not only to insanity but to other nervous diseases, as it is important to remember, occurs generally on the maternal side. Dr. Macdonald reported sixty-six cases, of which seventeen, or about 25 per cent., gave histories of family predisposition. Dr. Gundry reports twenty-two out of fifty-six patients, or about 50 per cent., who were predisposed by heredity. Of my own cases, four were descended from families with undoubted taints of insanity, or about 33 per cent. This gives an aggregate of 137 patients, of whom forty-three were predisposed to insanity.

Constitutions enfeebled by alcoholic or sexual excess, or by organic disease, are predisposed to attacks of puerperal insanity.

Another important, but decidedly difficult, point to observe, is the moral and mental habits and surroundings of the patients; and perhaps it is well to notice here the fact presented especially by the French alienists,—that unmarried women are much more liable to attacks of puerperal insanity than married ones. The sad amount of illegitimacy which is said to have existed in Paris has added greatly to the numbers of the insane during the period under consideration. The injurious effects of painful emotions were so well known in ancient Rome that it was the custom to suspend a crown from the doors of houses where women were in labor, to indicate that such houses were to be held sacred from all intrusion.

It is difficult to estimate the effect of education and culture in this phase of insanity. Statistics on this point are meagre and unsatisfactory, but I think I may safely say that, allowing the manner of living in two cases to be equally conducive to physical health, the better-educated woman is the least liable to puerperal insanity.

Under this head may be classed those cases where the attack is immediately preceded, and evidently caused, by some powerful mental impression; and also many cases which arise during instrumental deliveries. Dr. Marce attributes puerperal insanity to the constitutional disturbance attendant upon pregnancy and the establishment of the lacteal secretion, and to the general shock to the nervous system which is the direct consequence of labor. Dr. Gooch's theory of its dependence upon the peculiar state of the sexual system which occurs after delivery, and Dr. Storer's reflex insanity, are both of similar explanation, and deserve careful attention in deciding the causation of the disease.

Another writer, in *Winslow's Psychological Journal*, gives a very similar explanation. He attributes the origin of the mental aberration "to reaction between a system predisposed to such derangements, and the normal physiological conditions which are found after confinement, just as in constitutions predisposed to tetanus or nervous delirium these will be developed after the slightest accidents or operations." The special influence of the physiological changes undergone by the uterine and nervous system is a very interesting field for study. During pregnancy new functions are assumed, new relations between the nervous centres and the growth and nutrition of the uterus are being formed. The not uncommon advent of diseases of the kidneys, lungs, etc., the change of habits necessitated by the condition of the patient, all culminating in the peculiar and supreme nerve-tension of the stage of labor, followed immediately, it may be, by exhaustive hemorrhage and the drain of lactation, form a chain of causes whose existence renders the escape of a single woman mysterious and providential.

Dr. Marshall Hall claimed for anæmia and exhaustion the principal places in the causation of puerperal insanity. Undoubtedly these conditions enter into

many cases, but the claim of Dr. Hall cannot be substantiated.

Sir James Y. Simpson raised the point of the connection of this disease with albuminuria.

The statistics of observers do not show any proofs of this theory, and in the three cases of my fifteen in which this question was investigated no traces of albumen could be detected.

The symptoms of the three varieties of puerperal insanity do not present any very characteristic points. Melancholia is most frequently the type of the disease in the period of pregnancy; perverted appetite, suspicious fears, and perversions of the moral element are often noticeable.

Dr. Bucknell says, "Every medical man has observed the extraordinary amount of obscenity in thoughts and language which break forth from the most modest and well-nurtured woman under the influence of puerperal mania; and, although it may be courteous and politic to join in the wonder of those around that such impurities could enter such a mind, and while he repudiates Pope's slander that 'every woman is at heart a rake,' he will nevertheless acknowledge that religious and moral principles alone give strength to the female mind, and that, when these are weakened or removed by disease, the subterranean fires become active, and the crater gives forth smoke and flame."

Dr. Marce gives the case of a woman who became hydrophobic soon after conception; she could neither drink nor bear any one else to do so in her hearing, nor could she cross a stream of water.

Of 155 cases collected by J. Batty Tuke, 28 occurred during pregnancy, over 20 per cent. In my cases, 6 occurred during pregnancy.

Of 783 cases reported by Macdonald, Gundry, Marce, and others, only 65 cases occurred during utero-gestation.

Of Dr. Tuke's 158 cases, 73 occurred during the period of labor; of my 15 cases, 3 occurred during the period of labor.

The mental symptoms are generally of the maniacal type, and may be either ephemeral, occurring during the passage of the child from the os uteri or the os externum, or they may come on later and last longer.

In lactation, 54 of Dr. Tuke's cases occurred, and 6 of my own. The melancholic type predominates during this period.

Puerperal insanity is the most favorable for recovery, while the insanity of lactation is least so.

The prognosis is unfavorable when inflammatory conditions accompany or supervene upon the mental state, or when the strength of the patient is diminished by organic disease, exhaustive discharges, and maniacal excitement.

The treatment differs very little from that of other similar cases of non-puerperal insanity. When it is possible, narcotics should be avoided in the treatment of puerperal insanity, according to Sir J. Y. Simpson; warm baths and alcoholic drinks serving to quiet the patient and procure sleep. This is not always possible, and then chloral, bromide of potassium, conium, and opium, may be relied on. A useful combination is a solution of chloral with a saturated tincture of hyoscyamus or chloroform.

The non-appearance of the menses at the normal period should be considered as an indication for medication to the end. Tonics, stimulants, and nutritive articles should be given when called for by the condition of the patient. Blisters and other counter-irritants are often of the greatest service.

TETANUS.—Surgeon Bhawanee Doss records (*Indian Med. Gazette*) a case of tetanus arising from retained placenta, and successfully treated with hydrate of chloral.

GLEANINGS FROM OUR EXCHANGES.

ALTERNATIONS IN THE INTENSITY OF DISEASES (*Popular Science Monthly*, March, 1874; from the French of Alphonse de Candolle).—Medical history proves, on the subject of epidemic and contagious maladies, a marked fatality at the time of their first appearance, followed by slowly decreasing violence from generation to generation. This diminution is not due to an alteration in the nature of the disease, but to the fact that, when an epidemic falls upon a population for the first time, the greater part of the individuals disposed to receive the disease are attacked and die in large numbers. Subsequent births are the offspring of persons who did not contract the disease, or, at the least, who contracted yet survived it; that is to say, of persons better constituted than others to resist the disease. By virtue of the ordinary resemblance of children to their parents or grandparents, the succeeding two or three generations will be less disposed to suffer from the epidemic; there will be a diminution in violence, or a temporary disappearance of the disease. In time this protective influence is exhausted, and a proportion of individuals arises in whom the malady will be severe, and among whom the law of selection will recommence to operate.

In general terms, heredity and selection must produce an alternation of intensity and relief in diseases. That variation must be more marked when the disease in which it takes place is fatal, and especially when it attacks youth.

Curative or preventive means which are sufficient in periods of light visitation lose a portion of their efficacy at the aggravated period.

This rule applies particularly to the use of vaccine as a preventive of smallpox, as is seen in the European population, which, having been slightly exposed to the smallpox after two or three vaccinated generations, found itself approximating to the conditions of a population in which the disease appears for the first time. The attack is not altogether so violent, but the return is evident; and all means of resisting it which would have sufficed fifty years since have become less efficacious.

THE PREVENTIVE TREATMENT OF POST-PARTUM HEMORRHAGE (*The Dublin Journal of Medical Science*, January, 1874).—Dr. A. H. McClintock calls attention to the fundamental principles governing the production of hemorrhage after delivery, viz., the muscular contractility of the womb, the state of circulation at the time of delivery, and the coagulable power of the blood itself. It is especially important to note the premonitory symptoms of the hemorrhage in question. Vascular excitement towards the end of gestation and during labor always forebodes hemorrhage. When the pulse is permanently rapid and jerking towards the end of labor, and whenever after delivery it ranges above 100, there is great risk of flooding. In the progress of labor, particularly in the second stage, the character of the pain affords a very reliable indication as to the probability of hemorrhage, which is likely to occur if the pains, instead of gradually culminating with a strong pain and subsiding, are sharp, quick, and cease suddenly, with long intervals in proportion to the length of the pains.

In adopting prophylactic measures, all that is required to secure the desired quietude of the vascular system is open-air exercise, abstinence from stimulants, and regularity of the bowels. The liquor amnii may be let off early in the second stage by artificial rupture of the membrane, thus rendering the uterine contraction more permanent and enduring by making it more gradual. The most effectual of all resources against post-partum flooding is ergot, which should be given some little time before delivery. Gallic acid and iron,

when the blood is inclined to be non-coagulable, have also been found to be of great service.

CROTON CHLORAL HYDRATE (*The Lancet*, January 31, 1874).—Mr. J. Burney Yeo, after a number of systematic observations, has come to the following conclusions:

1. In croton chloral hydrate we possess a remedy of remarkable efficacy in some cases of neuralgia of the branches of the nervus trigeminus. 2. It has also the power of affording relief in other obstinate forms of muscular rheumatism. 3. It is of use in certain cases of diffused purely rheumatic cases. 4. It has but little effect in purely rheumatic cases. 5. In cases of localized pain and other nervous symptoms which we find in the class of persons we are in the habit of calling hysterical, this drug is of little or no use. 6. Its efficacy in procuring sleep seems very variable in moderate doses. Two grains will produce sleep in some sensitive females, while ten grains will not even cause drowsiness in non-sensitive males. 7. It is very valuable in some forms of irritative and spasmodic cough, and there is scarcely any remedy likely to prove more valuable for the relief of the distressing night-cough of chronic phthisis.

The dose varies from one to ten grains. From two to five grains may be given every hour, or the smaller dose every half-hour, until fifteen grains have been taken. At present it hardly seems safe to go beyond that dose.

The subcutaneous injection of twelve grains in a cat produced, after prolonged unconsciousness, a series of epileptic convulsions and death.

THE STYLOID MUSCLES AND ANÆSTHETICS (*The Boston Medical and Surgical Journal*, February 26, 1874).—Dr. S. W. Copeland gives the following explanation of the irregular and obstructed breathing which so frequently occurs at a certain stage in the administration of anæsthetics, the patient being in the usual sitting or recumbent posture, with the head held back:

The styloid muscles are put on the stretch. The stylo-glossi draw the tongue backwards, the stylo-hyoides draw the os hyoides upwards, and the stylo-pharyngei raise the pharynx and thyroid cartilage upwards, all thus uniting to close the epiglottis. Pulling out the tongue will partially overcome the action of the stylo-glossi, while the other muscles will maintain their action.

If now the head be tilted forward, the styloid muscles are all relaxed, the tongue falls forward in the mouth, and the larynx falls into its proper place, thus leaving the epiglottis free and the glottis unobstructed, and establishing regular respiration through the natural channel of the nose.

TURPENTINE IN PYÆMIA (*The Lancet*, January 31, 1874).—Dr. J. Sinclair Holden relates the case of a workman in whom amputation of the fingers was rendered necessary by an accident. Gangrene supervened, a secondary operation was performed above the wrist, and was in its turn shortly followed by rigors, profuse sweats, sleeplessness, low delirium, subsultus, and stupor, the wound becoming sloughy and offensive. The man rapidly sank, in spite of free stimulation.

As a *dernier ressort*, half-drachm doses of turpentine were administered in egg emulsion every four hours. After the third dose they were discontinued, as the pulse and temperature had fallen and consciousness returned. The patient partook liberally of brandy and beef-tea, but on the following day all the asthenic symptoms reappeared, and the patient relapsed into a comatose condition. The turpentine was again had recourse to, and with the same happy effect. This time the improvement was permanent, and the patient made an excellent recovery.

CEREBRO-SPINAL MENINGITIS (*The Lancet*, January 10, 1874).—At a meeting of the Medical Society of London, Dr. Dowse read a paper on the above subject, and gave the following diagnostic table:

EPIDEMIC CEREBRO-SPINAL MENINGITIS.	SPORADIC OR BASIC CEREBRO-SPINAL MENINGITIS.
Attack sudden, without any special predisposing cause.	Attack commences gradually, and resembles an onset of acute rheumatism.
Apparently of a contagious or infectious origin.	Usually arising from exposure to cold, exhaustion, and privation.
Sensorium affected from the first.	Sensorium never affected until the last stage.
Excito-motor spasms of a tonic character in groups or groupings of muscles, with marked loss of cutaneous and muscular sense.	Incoördination of movement, with cutaneous formication, partial anæsthesia, muscular hyperalgia, but no tetanic spasms.
Reflex movements common.	Reflex movements rare.
Vomiting urgent and uncontrollable.	Vomiting not so severe.
Temperature rarely exceeds 100°.	Temperature often rises to 105°.
Purpuric maculæ diffuse and general.	Maculæ never seen in the desudate form.
Death usually takes place from coma.	Death usually takes place from apnoea.
Prognosis grave.	Prognosis hopeful.
Post-mortem appearances reveal the membranes over the superior cerebral convolutions and posterior columns of the cord as the seats of lesion.	Post-mortem appearances reveal the membranes over the base of the brain and anterior column of the cord as the prime seats of lesion.

MISCELLANY.

GLYCERIN FOR PRESERVING FRUIT.—We learn through a German journal that in order to preserve fresh fruits it is only necessary to heat them, if not perfectly ripe, in water almost to boiling, drain nearly dry, and cover with warm, concentrated glycerin. If the fruit is perfectly ripe, heating in water is unnecessary. It is also advised to pour off the glycerin after standing for some time, and add fresh concentrated glycerin. The glycerin poured off may be concentrated on a water-bath and used a second time. Ordinary glycerin is often impure, but only that which is perfectly pure and colorless, with a clean, sweet taste and a specific gravity of 1.25, should be employed.—*Journal of Applied Chemistry*.

A MEDICAL LICENSE FOR LADIES.—The King and Queen's College of Physicians in Ireland has determined to admit females to the examination for its diploma in Midwifery, which can be registered. The Royal College of Surgeons in England has the power of granting a license in Midwifery, which can be registered. If it would use this power in favor of women passing a fit examination, we might hope for some abatement of the scandal of midwives' midwifery, and see an experiment on a goodly scale of the fitness of women for midwifery practice, which we much question.—*The Lancet*.

PRESERVATION OF FOOD BY GREAT COLD.—M. Bous-singault (*Comptes-Rendus de l'Acad. des Sci.*, January 27) states that a quantity of beef-tea having been submitted, eight years ago, to a temperature of -20° for several hours, has remained in perfect good condition up to the present time. Sugar-cane juice was at the same time subjected to this treatment, and was found to be in excellent condition. Both substances had, of course, been kept in closed vessels.—*Druggist's Circular*.

NOTES AND QUERIES.

HOSPITALS AND MEDICAL PROGRESS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

It may be that you have correctly indicated "Some of the Uses of Hospitals" in a recent article,* though in disposing so summarily of the part which provincial practitioners can and do play in medical progress it seems to me you have fallen into error. In my time, so far from medical progress emanating from hospitals, it has emanated more from the people than the profession.

The real spur to medical progress, if I have interpreted the signs rightly, is the patronage people bestow on irregulars and patent medicines. This would not be the case were the people satisfied with the ministrations of the regular profession to the sick. Speaking of and for myself, the enormous extent of the traffic in proprietary medicines, and the patronage given to irregulars, have been a spur to me all my professional life to make myself a safer and more trustworthy guide in sickness to-day than I was yesterday. Advancing age, and its consequent experience, have had something to do with my own progress, if I have made any, in my thirty years of professional life. I have had many very useful hints, suggestions, and instruction from others, few of whom were, however, connected with the staffs of great or small hospitals.

Hospitals ought to do the duty through their staffs, you point out; but the truth is, they have not in the past, and are not doing so now. In my time, and so far as I can read history in the past, progress in medicine originates in the study, or rather the studies, of private practitioners. Hospitals have sometimes settled unsettled points of administration. They have settled many points in physiology and morbid anatomy. But, I apprehend, everything which post-mortems, by unassisted vision, can settle, has been settled long since, and now needs no repetition, except for the instruction of novices. Many points in physiology need further investigation with assisted vision, but I believe that, since the publication of the recent elaborate works on histology, the limit of useful discovery is nearly reached in that direction.

The path of real progress in medicine, it seems to me, lies in arranging the accumulated facts in the several departments of medicine in a plan or science of life. Aimless and pointless "experiments" with "drugs and medicines" will contribute little of value to the coming science of life, except to weed out needless therapeutic measures; and this they can do much less perfectly as empirical experiments, than with a well-defined purpose and end, in a science of life.

So far from medical reforms and medical progress originating in and radiating from the staffs of hospitals, they obey the law common to all other progress in knowledge and reforms, and originate on the outer borders, with those who come in contact with their fellow-beings in private life,—the general practitioners.

The educated classes in civilized life have, in many instances, outgrown medical philosophy as it exists to-day. They look for the same definiteness in medicine that they find in other departments of human knowledge. The irregular practitioner and proprietary medicine vendor proffer them this definiteness in their "theories" of disease and cure, and obtain enormous patronages, and accumulate wealth. The number of those who become dissatisfied with regular medicine is always large enough to supply them material upon which to ply their trade.

In medical centres, medical progress, except in limited directions, is effectually barred by medical ethics. Whoever attempts to teach in a medical centre, must teach up to the standard of the text-books. Any departure of moment would forfeit his standing in the profession,—he has violated medical ethics. To teach, he must found a new "school" of medicine. The direction of progress recognized by the ethics of the profession is "observation" and "experimentation." If an attempt is made to deal with the results of observation and experiment by the only other mode by which the boundaries of knowledge are enlarged, viz., abstraction, the ethical fingers of the profession beckon him to desist, or he will lose caste. In truth, the channels of professional education are full, and any material change in any department would mean new men at the front. There are, therefore, many reasons for preserving the *status quo* of the profession in medical centres, not least among which is "Nestor's" admonition not to attempt innovations, or "bread and butter" will be lost. Medicine of to-day is encumbered with a nomenclature and ideals which cannot be carried forward into a science of life. Much of its nomenclature is hoary with age, some of it blended intimately with superstition or tradition, and cannot now be used to designate or represent exactness. Definitions of many of the terms have been modified from time to time, to correspond with the changed and changing knowledge or "views" of the things or processes they are intended to represent, until their original sig-

nificance has been lost. This applies to written definitions. Despite this, the old significance is the prominent thing carried forward, orally and mentally. Inflammation and tubercle are instances of these attempted modifications of meaning.

There are, however, some significant signs from influential quarters, looking towards the employment of "logical" methods of investigating life-phenomena. Thus, Prof. Flint,† under the cover of discussing "the contagiousness and non-contagiousness of disease," presents a plea for the use of "logical" methods of dealing with certain "accumulated facts" of life; that is, "abstraction." True, portions of his paper would not bear the touch of logic, for he speaks of "disease" in the old sense, as something tangible, real, and distinct from the living body. And that is the conception of ninety-nine hundredths of the people, and probably the profession, including irregulars. But it is, perhaps, needful to mingle the old and new in this confusion, to obtain a hearing.

This mania, if I may so speak, for experimentation and observation, on the part of the profession, reminds me of a patient to whom I was administering chloroform some years since. Her breathing and pulse gave me timely warning of danger, yet, whenever consciousness returned, she would call out lustily for "more chloroform." So it is with the profession; though overwhelmed with facts, the cry is still, "Give us more facts." It is pleasant to know that what is wanting is not new facts, but the arrangement and classification of those already made out, in the frame-work of a science of life. I say frame-work: for a complete science of life, whose chief factors are motion of matter, or motion by matter, will never be attained. A thing complete would be only a system, like homœopathy, hydropathy, etc., etc.

The lines to guide future investigation, whether by experimentation, observation, or abstraction, are laid down definitely and sharply in the brief introduction to an authority second to none in the profession.‡ And, to my mind, there are now no essential facts wanting to construct a science of life, with places for all the new facts which present and future investigation will continually bring to light. The adoption of such a scheme will, or should, limit unnecessary observation and experimentation. For, when a point is once demonstrated, that ought to put an end to investigation concerning it.

The missing link needful to connect in harmony all the results of past investigation, is the function I have assigned to the lymphatic system.§ Its use, or physiological function, was arrived at by induction,—abstraction,—and bears the severest tests of the "logical" methods of Prof. Flint in dealing with the problem. It seems to me past "hospital reports" may, without injustice, be placed with the volumes you so recently pronounced as ranking *zero in worthlessness*, for each contains some valuable matter.

"Hospital Reports," if got up with reference to the lines of investigation laid down by Rindfleisch, may be placed alongside of that which you designated *acme of excellence*. In the educated popular mind, the profession—regular profession—has but an equivocal standing. Witness the onslaught on it, on a recent occasion, by certain influential secular and religious journals in the cities of New York and Cincinnati. Medical literature was branded by the *Cincinnati Gazette* as "medical balderdash;" while equality in public practice was claimed for homœopathy in New York and Brooklyn, on the score of equal fitness for the service.

These now at best lukewarm friends will become warm friends when the logical test is applied by the profession in dealing with the facts of life,—not before.

Z. COLLINS McELROY.

ZANESVILLE, OHIO, February 16, 1874.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting will be held March 25, 1874, at 8 o'clock P.M., at the hall of the College of Physicians. Dr. William Pepper will read a paper on the "Diagnosis and Treatment of Pleural Effusions." All regular practitioners of medicine are invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 10, 1874, TO MARCH 16, 1874, INCLUSIVE.

RANDOLPH, JOHN F., SURGEON.—Relieved from duty with Sioux Expedition. S. O. 35, Department of the Platte, March 11, 1874.

BILL, J. H., SURGEON.—Granted leave of absence for thirty days. S. O. 55, Military Division of the Atlantic, March 12, 1874.

O'REILLY, ROBERT M., ASSISTANT-SURGEON.—Assigned to duty with Sioux Expedition. S. O. 35, c. s., Department of the Platte.

ORIGINAL COMMUNICATIONS.

THE SUPPLY OF NERVES TO THE SKIN.

BY S. WEIR MITCHELL, M.D.

I PUBLISHED in the *Times* of December 6, 1873, a brief sketch of my opinion in regard to neurotomy, and as to certain questions which are related to nerve-sections. The views of this paper were criticised by Dr. H. C. Chapman, in the *Times* for January 24, 1874, and grave fault was found with my anatomical facts. Had my knowledge of anatomy been the only point concerned, I should have made no reply; but if Dr. Chapman's confident defence of the Anatomies be accepted, it will lead to the belief that we possess, in ample amount, a certain kind of knowledge which, in reality, we have not, and this I regard as of moment, and as making an answer necessary.

In the paper above mentioned, I stated that surface-nerve anatomy, as taught in the books,*—and I except none that are known to me,—is a fiction. If I had said there is, as yet, no definite and precise surface-anatomy, it would have been a more sweeping statement, and yet would have been correct. Dr. Chapman thinks mine an extraordinary assertion, and “will try to show that, so far from surface-anatomy being a fiction, not only in its general features but in detail it has been made out correctly for years.” Then follows a long and clearly-written account of the general distribution of nerve-branches in the fingers.

Nothing beyond a careful reading of this could be needed, by a thoughtful reader of my own paper, to prove from what different points of view Dr. Chapman and I are looking at the subject of surface-nerve anatomy. He is content with a description which tells us that this nerve-filament supplies the *side* of this finger and these anastomosing filaments feed adjacent *borders* of these two fingers, or the *ends* of such-and-such fingers are supplied by branches of median and ulnar nerves, etc. In Dr. Chapman's surface-nerve anatomy it is rather curious that the word *skin* is not once used, nor is any analogue employed. The nerves feed the *ends* and the *sides* of fingers, etc. Now, this is not *surface*-nerve anatomy as I wish to see it made out, nor could any one dream from his drawing that the skin-distribution is other than symmetrical, nor from his description, written with intent to show how well surface-nerve supply is understood, could it be suspected what precise areas of skin are supplied by certain nerves, or even that the skin is supplied at all. It is, nevertheless, pretty sure that as a rule each nerve supplies largely certain rather definite skin-spaces, that it supplies with far fewer filaments other cutaneous areas, while to some it sends so few fibrils as to be in such regions of trifling functional moment. It is not enough to say, for exam-

ple, that the median supplies branches to the “tip,” “to the back,” “to the parts beneath the nail of the index-finger.” How much of the back of the finger does each nerve innervate? In what proportion do any two nerves concerned feed the same skin-spaces? In other words, if we cut the median, where will pain and touch be lost, and to what amount will they suffer in the various regions fed? Surely, if true surface-neural anatomy be known, there is no need to ask an answer of the clinic and the laboratory. Certainly no anatomical description traces for me the exact skin-spaces in which each digital nerve terminates. The drawings in the books like Dr. Chapman's, or properly, I suppose, my friend Leidy's, mislead us into a notion of symmetrical distribution of the nerve-endings in the skin which does not hold good; and diagrams such as exist in Flower and Henle still further bewilder, and are scarcely more than an approach to the truth. The fact that more than one nerve may be concerned in feeding each portion of skin makes the question of greater moment. If, at certain parts of the skin of the end of the dorsum indicis, an injury exists which it becomes desirable to quarantine by a nerve-section, it is, of course, well to know which of two nerves to cut first, as we might not wish to cut both at once. The exact limit of distribution, the proportional feeding of skin at this part by each nerve, would here be a thing of importance to know; and this no anatomy gives, for this would be surface-nerve anatomy, which is as yet in its infancy. Or, should I seek to learn just how much of the skin of the face will lose the sense of pain and touch after section of the infra-orbital nerve, no anatomy shows this. I ought to add that my own nerve-sections give the spaces in question, and that on the back of the index-finger and of the medius, as I shall elsewhere show, the region of lost pain and touch after section of the median is such as no one could define from any anatomical description or drawing to be found in the books. This brings me to say a few words as to another fact. I said in my paper that the median nerve sometimes *innervates* the thumb, index-finger, and half of the medius, sometimes reaches the whole of the medius, and very often extends over half of the annular. Dr. Chapman is in part right when he blames this statement; but it is a good illustration of the need for a knowledge of proportion in nerve-supply. The facts are valuable, and I shall give them briefly. It will be noted that I say the median innervates; and I said it for this reason, that the subcutaneous nerve-supply seems sometimes to be anatomically large, when really it supplies but little function to the skin,—does, in fact, hardly innervate it. Thus, in France, Létievant has given cases of median section in which the loss of palmar feeling is said to have extended in one to the middle of the median finger, in another to the line between it and the annular, in a third to the middle of the annular. I have seen two median nerve-sections; in both the sense of pain and touch were wholly lost in the face of the thumb, face of the index, and of half of the medius. One I examined no further;

* As Gray, Wilson, Sharpey and Quain, Hyrtl, Leidy, Luschka, Henle, Rüdinger, Hirschfeld and Léveillé, Cruveilhier, Sappey.

the other has full sense of the position of a touch and of the lightest contact beyond this line. Tested by the compass-points there is, however, lessened feeling in the palmar aspect of all the fingers save the little finger, even in the ulnar half of the annular, which is beyond the region usually given to any median supply. In other words, the median supply of innervation was ample in the thumb, index, and half of the medius, but beyond that only capable of measurement by delicate instruments.

Whether these facts be due to variations or to a greater difference in the proportional distributions than seems to show in the books, I cannot yet say. They explain, however, those statements of my last paper with which fault has been found. In a special case mentioned, Dr. Chapman asks further why I should have been astonished at the fact that after section of the radial nerve touch seemed to be nowhere lost. Somehow, this is an astonishment which still clings to me, because in two other cases of radial section, of which I have notes, there was considerable loss of touch-sense, and even, in a quite limited area, of pain-sense. Also, this is what Létievant found in his sections. Therefore, in one case which seems to have been well observed, a cut radial left the dorsal hand-surface in full function. In others the loss of pain and tact existed in a small space on the radial side of the dorsum, while elsewhere, over nearly all of the back of the hand and fingers, touch was lessened. There was, therefore, I think, some cause in my case for my being astonished. Dr. Chapman's reason for feeling no amazement at the continuance of full touch-sense in the dorsum of the hand and fingers arises, as he tells us, from the fact that, supposing the radial were cut, the back of the hand would still be supplied by branches of the "*external and internal cutaneous, dorsalis ulnaris, and the interosseous* nerves." The radial nerve, however, according to every writer, supplies largely the skin of the back of the hand, and it does, therefore, seem strange, unless he attributes the fact to something unusual, that Dr. Chapman should suppose its loss would give rise to no defect of sensation. It will be remembered that in quoting my case I was alluding to the possible occurrence of variations in nerve-supply.

The doctor mentions the interosseous nerve as aiding to make up any lack of feeling in the skin of the dorsum of the hand due to loss of the radial nerve. Of course he refers only to the posterior interosseous; but no authority describes this nerve as affording *any* such skin-supply. It feeds only the wrist-joint,—possibly, according to Knox, some areolar tissue, while Rudinger and others trace fine filaments to the metacarpo-phalangeal joints of the fingers. Unless Dr. Chapman has made new dissections which trace it elsewhere, this nerve must be left out of the case. It is a matter of small moment; but, having been read a lesson on anatomy, it is pleasant to be able in turn to afford some instruction to so able and minute a critic.

Again, I said that after section of all the cords of the plexus save the external, the palm and dorsal surface of the hand, fore-arm and arm, and the inner face of the arm, retained tactile feeling. I

said that this surprised me. My critical friend does not see why, "because," he says, "the external cord forms part of the median and the external cutaneous, the very nerves supplying the parts which retained the touch-sense." "Indeed," he adds, "I should have been surprised had it been otherwise." Therefore, according to Dr. Chapman, the external cutaneous and a part of the median ought to be enough, without the ulnar,* radial, part of the median, musculo-spiral, internal cutaneous, and lesser internal cutaneous nerves, to give such touch-sense in the parts named as to cause no surprise to a reasonably trained observer. Of course, for the fact in question there is some explanation, but it singularly impressed me and others at the time; and not so much because of there being some touch, but because the man gave the locality of the touch alertly, and seemed to feel so very light an impact.

I must be pardoned yet one reply. I stated, in a guarded mode, that cold, pressure, or galvanism may help us, in cases of doubt, to discover the presence of variations of nerve-supply. It would have been difficult to state in a more careful way the merely possible value of a proposed new means of inquiry. Dr. Chapman, however, thinks that any result based on such a mode of experimentation would be very unreliable, because of the free anastomoses of nerves. What Dr. Chapman means by the anastomoses of nerves he does not say. If he means merely the constant gross interchange of fibres which is so common, his criticism is valueless, because such anastomoses are purely anatomical, and so a paralyzing impression made, for example, on the ulnar nerve at the elbow will simply affect the definite peripheral area supplied by the nerve-fibres present in this nerve at the elbow. There is, as yet, no certainty as to the existence of true nervous anastomoses in the extremities; that is, of nerve-tubules directly communicating and transmitting impressions from nerve to nerve; nor, if we had the knowledge of such anastomoses, would we be as yet justified in assuming for them an exact physiological value. The chiasms of the laryngeal nerves in some animals seem to have no physiological uses, and the nerve-filaments which cross the median line of the body in the frog appear to possess power to transmit impressions; and so the most intimate terminal relations of nerve-filaments do not in our present state of knowledge permit us to feel sure that they are the means of carrying impressions from the territory of one nerve into that of another. I am unable, therefore, to see what was meant by this criticism.

Then I am told that the pain which attends such experiments vitiates them, because it is an abnormal condition; but pain, in its milder forms at least, a

* The external cord of the plexus gives off the musculo-cutaneous nerve, and about one-half of the median; whether or not it helps to make up the ulnar, must probably remain undecided during life in any individual. In Cruveilhier and in Hirschfeld and Léveillé the diagrams represent the ulnar as receiving a branch from the external cord; but, although Leidy so describes it, neither of the other two anatomists recognizes this origin in its text, which seems strange enough. Henle recognizes the origin from the external cord as sometimes found. A recent study in this city of the variations of the plexus in thirty subjects, by Mr. Walsh, student of medicine, resulted in finding no one instance of partial origin of the ulnar from the external cord. Mr. Walsh has kindly put in my hands a résumé of his results; but, as he will publish the full study of over one hundred cases, I refrain from further quotation.

physiologist should know, is hardly to be called abnormal,—is, in truth, as distinctly a function as is touch; but in fact I said of my three proposed methods that one of them—freezing—was “very painful;” that pressure, the second, “was not painless;” and as to the third, electricity, I spoke of currents of “moderate intensity,” of “mild currents;” and where is this pain, which is supposed to vitiate a method which the critic seems never to have tested, and which, whether good or worthless, is certainly not open to his forms of objection?

One word to close. The anatomies teach thoroughly sub-surface nerve-distribution. No anatomy gives the true areas of nerve-supply to the skin; not one gives the proportions of this supply.

At the best we are told that the skin of the end of the dorsum of a finger is fed by this nerve or that, the skin of the face of this finger by one nerve, that of its side by another. No book delineates the limits of distribution, and whatever attempts have been made in the anatomies to describe the true surface-supplies are shown to be false by clinical experience. This cutaneous-nerve anatomy is to be made anew, and we want to see in the books tinted maps giving the limits and proportional distribution of nerves to the skin. With novel methods and a fuller knowledge of what is known and what is not, but especially with the help of clinical nerve-sections, we shall soon come to understand correctly how much of the skin each great nerve supplies, and, on the other hand, how much of each nerve goes to effect this object in particular areas of skin. Accurate nerve-supply to the skin, and its proportions—this is what we want. Until we get our knowledge, I shall still be forced to believe that our present surface-nerve anatomy is a fiction.

DISLOCATIONS OF THE HIP—SCIATIC VARIETY.

BY OSCAR H. ALLIS, MD.,

One of the Surgeons to the Presbyterian Hospital.

SIR ASTLEY COOPER considered sciatic dislocations the most difficult to detect, and Syme has unwittingly confirmed this opinion, by once failing to recognize the injury and leaving it unrestored for fourteen days. If further evidence is required of the difficulty of diagnosis, I will refer to the following cases, two of which passed beyond the power of remedy before the true nature of the injury was detected.

Case I.—J. K., æt. 61, was brought into the Presbyterian Hospital in July, 1873. History of the case: During the night of the Friday preceding his admission he walked in his sleep from the second-story window. In his descent he struck a clothes-line, which broke, and in a measure changed the direction of his fall; but as the accident occurred in the night, and during sleep, it was impossible to gain fuller particulars.

I first saw him lying on his bed; the right thigh was flexed on the pelvis, and stood awkwardly off from the body. On assisting him to assume the erect posture, I noticed that the toe of the right foot could with difficulty be brought to the floor; that the heel was drawn

up; that the ham-string tendons were rigid and prominent; that the leg was flexed on the thigh, and the thigh on the pelvis; that the knee was turned inward towards its fellow; that the gluteal region was flattened and apparently widened; that the spinal column was arched forward in its lumbar region, and that the trunk and extremity had assumed an awkward, constrained, and helpless position.

Upon the administration of ether the limb was brought down by its fellow, and a shortening of half an inch observed.

The reduction was accomplished in the following manner: The man was placed on the floor; then an assistant held the pelvis, while two others, by means of a fillet placed above the knee,—the force being exerted at right angles to the plane of the body,—lifted the head of the bone to a level with the acetabulum. This being done, I was enabled, by grasping the ankle with one hand and the knee with the other, to convey the dislocated bone into its proper place, though with a scarcely audible sound.

There was some difficulty experienced in dislodging the bone from its new position, and the instant it took place crepitus was distinctly recognized by all present.

The patient, after reduction, was placed in bed with the usual restraints; but, as lying in bed was irksome to him, he arose from it in about a week, and, experiencing no difficulty in walking, did not return to it by day, and was soon discharged at his request from the hospital.

Case II.—Mrs. G., æt. 64. Fell on going into the yard down a flight of six steps. She thinks she received the force of the fall in the middle of the thigh posteriorly.

As she was rendered helpless by the fall, the family physician was sent for, *who, on learning the nature of the accident, and fearing, from the age of the patient, a fracture, administered ether, gave her a careful examination, and, as neither deformity, crepitus, nor restricted motion was present, left, satisfied that it was only a contusion.*

Five months later—the patient in the mean time being helpless on account of the great suffering in the part—I saw the case. There were present the following symptoms: Shortening of about half an inch; the limb lay parallel with its fellow, with the toes looking upward; the limb, especially below the knee, was œdematous. The knee was stiff (false ankylosis). The gluteal region was flattened and apparently widened. The gluteo-femoral creases of the two limbs did not correspond as they do in the normal condition, and the great trochanter could be distinctly felt in its new position. There was great pain in the limb, constant, and aggravated by changes in the weather, and referred to a point in the course of the great sacro-sciatic nerve, about six inches above the popliteal space, and due, probably, to the head of the bone resting on and compressing the nerve at its exit from the pelvis.

The patient was again brought under the influence of ether, as every motion of the limb was painful, and the diagnosis of sciatic dislocation was established. There seemed to have been no adhesions, or at least no difficulty in breaking them up, and during manipulation and traction the head was distinctly recognized to jump suddenly from its new bed. This feeling we all experienced two or three times under the repeated efforts* made to restore it, but our exertions were fruitless.

Case III.—Mrs. R., æt. 57, fell to the sidewalk on a slippery evening in February, 1872. She fell upon her left thigh, but by some means the injury sustained was in the right. As she was unable to rise, two policemen

* Our efforts were with a view to dislodge the head of the bone and form a new home for it if it could not be restored. We failed in both.

came to her assistance, and one of them stooping to help her fell across her outstretched right limb, and it is more than likely that to the second accident is her present condition traceable.

On being conveyed to a friend's, a physician was summoned, who examined her *lying on a feather bed*, and with *all her clothing on*, and pronounced "no bones broken." Not satisfied with his opinion, another physician was summoned the following day, who, after a careful examination, said that the injury would not "signify," and clapped on a large fly-blister!!

I will not repeat the needless, superadded suffering of the poor woman from a mistaken diagnosis.

As soon as the limb had recovered from the shock—*i.e.*, within a few days—she had rotation, and found the easiest position for it to be *semi-flexion*. She sat up in a few weeks, and left her bed in four; though from the receipt of the injury to the present time she has been unable to walk without crutches. Pain has been a constant, persistent feature from the first.

Present condition (the patient standing before me).—There is marked flattening of the gluteal region. The spinal column is *not* unusually arched forward. The limb has a natural, easy position, with three-fourths of an inch shortening. She can place the foot as flatly on the floor as she ever could, and can stamp and kick out with it with considerable force. The measurement around the pelvis on a level with the pubes shows that the injured hip is less prominent by one inch and a half. The head of the bone has not formed adhesions in its new home, and can be moved as freely as the sound one. The great trochanter is one inch farther from the *pubic symphysis* than its fellow; and a resort to the following device establishes the nature of the injury.

In the cases above described will be found the symptoms that characterize *recent* or *chronic* sciatic dislocations: hence a summary of them will not be given. To arrive at a correct diagnosis in all severe injuries of the hip is a matter of the greatest importance, and to aid in this I would suggest the following simple but effective plan.

FIG. 1.

POSITION IN WHICH TO TAKE THE FIRST MEASUREMENT.

Place the person on a hard mattress, or, *better*, the floor, and notice the amount of shortening, if any, with the limbs in a line with the body. If it be sciatic dislocation it will not exceed three-fourths of an inch; there may be none.

Next compare the limbs at right angles to the trunk (Fig. 2), and if it be a sciatic dislocation there will be a difference of at least *one inch and a half*; but if the measurements in both positions are the same, there cannot by any possibility be a sciatic dislocation.

To understand the philosophy of this plan it may be of importance to examine a pelvis (Fig. 3), placing it in the position of a person lying on his back. The great sacro-sciatic notch now lies *an inch and a half* almost directly below the acetabulum, so that it is quite possible (Case II.) for the head to lie in it,

especially immediately after dislocation, and exhibit no shortening by the usual mode of measurement.

FIG. 2.

POSITION IN WHICH TO TAKE THE SECOND MEASUREMENT.

But the instant the femurs are compared at right angles to the plane of the trunk,—as indicated by the perpendicular lines,—a marked difference is at once effected.

Now, there is a principle involved in this of great practical importance. It bears upon every variety of obscure injury at the hip, whether it be dislocation, impacted fracture, or severe contusion. The principle is this. While the heads of the femurs lie in their respective acetabula, corresponding measurements in every position will not vary. If one thigh is half an inch shorter than its fellow (as may be possible in impacted fracture) the same difference will persist in flexion, extension, abduction, or adduction.

FIG. 3.

But not so in dislocation. Here the head of the bone is fixed at a point that does not correspond to the acetabulum, and in every new position in which the limbs may be compared a different result may be expected.

A correct diagnosis in injuries of the hip is of the utmost importance to all concerned. Simple injuries, as a fall upon the great trochanter, are often most disastrous, and are frequently followed by years of suffering and helplessness; and it is certainly the part of prudence, not to mention humanity, to make repeated careful examinations and under the most favorable circumstances, and thus, before it is too late, rectify any mistake that must otherwise be followed by a lifetime of suffering.

To Drs. Truman and Yocum, and Mr. Charles Neill, I am indebted for valuable assistance in the first case recorded.

DESCRIPTION OF SPECIMENS FROM DR. LEVIST'S CASE OF ANEURISM OF THE SUBCLAVIAN ARTERY TREATED BY THE INTRODUCTION OF HORSE-HAIRS.

BY MORRIS LONGSTRETH, M.D.,

Curator to Pennsylvania Hospital Museum.

Read before the Pathological Society of Philadelphia.

JAMES M., æt. 47, was admitted to the Pennsylvania Hospital with a large aneurism of the right subclavian artery. It had been recognized only three weeks previously, although he had had pain in the right chest and arm for nine months. A pulsating tumor with distinct aneurismal thrill was seen jutting above the clavicle, and below that bone another swelling was felt, in which the thrill was almost absent. Horse-hair was introduced through a fine needle canula; no difficulty was experienced in its introduction, and twenty-four feet nine inches of it were safely stowed away in the aneurism. The tumor became hard, and pulsation in it and in the radial ceased. No local irritation occurred in or about the swelling after the operation, nor any inconvenience from the arrest of the circulation.

The patient died November 16, 1873, with symptoms of engorgement and pressure on the upper lobe of the right lung. The expectorated mucus was darkly colored with blood.

The autopsy was made some hours after death. There was some œdema of the axillary and pectoral regions, as well as of the right arm.

On the removal of the pectoral muscle, the whole region around into the axilla and under the scapula was fluctuating.

On opening the thorax, the upper lobe of the right lung was found solid, of a dark-red color, and pressing close up to the mediastinum. The margins of this lobe, however, were still crepitant and of their normal color.

The lower lobe was collapsed.

The right pleural cavity contained a small amount of blood-stained serum, but there were no evidences of inflammation.

The aneurism commenced in the second portion of the subclavian artery, at an inch and three-quarters from the bifurcation of the innominate. The wall of the vessel had given way upwards and downwards.

The upper dilatation was about an inch and a half in diameter, and reached above the clavicle, partially covered by the fibres of the scalenus anticus muscle. It contained a dense white clot.

The opening on the lower wall of the vessel was oval-shaped, about an inch in its greater diameter. The margins of this opening were smooth and quite regular.

On dividing the upper lobe of the right lung, there was found a mass of black clotted blood behind it and extending beyond the line of the ribs, especially in the axillary region immediately below the clavicle, nearly two inches. In the upper portion of this soft clot a dense white clot was found attached around the lower aneurismal opening in the subclavian.

In the posterior part of the fibrinous clot were found the horse-hairs.

The lung appeared to have been pressed forward and inward by the increasing mass of blood behind it. Its vessels and the bronchial tubes had been occluded by its condensation. The lung-tissue in contact with the clotted blood resembled the condition of a lung in hydrothorax.

It was found that the first and second ribs had almost entirely disappeared; from the third to the fifth the ribs had been stripped of their periosteum; on the inner surface of the sixth rib the process of stripping was seen going on, the pleura and periosteum were slit for

about an inch, and the blood had forced its way underneath them and almost surrounded the bone for this distance. The third, fourth, and fifth ribs maintained their normal position, but the blood extended through the costal interspaces, so that the clot in the thorax communicated with the fluctuating mass found beneath the pectoral muscles. Hence it will be seen that the fluctuating tumor in the axilla was covered with the dense fibrous tissues of the pleura, intercostal muscles, and costal periosteum, which had been pressed outward by the blood accumulating in the thoracic cavity. The intercostal vessels were found lacerated.

An experiment was made to determine whether or not the blood-current in the subclavian communicated with the black clot found in the thoracic cavity, but it was found that water poured into the aneurismal dilatation of the vessel was perfectly retained, none escaping into the thoracic cavity. On very careful dissection, this fact was proved, for it was found that the mass of fibrinous clot in the dilatation varied from a half-inch to two inches in thickness on the circumference.

Diligent search was made for coats of the dilated vessels, but it was impossible to trace them beyond half an inch from the margin of the opening. The cavity in the fibrinous clot was about two inches and a half in diameter, extending downwards and outwards from the opening in the vessel, having the horse-hairs imbedded in its posterior walls. In the fresh condition this cavity was filled with a recent black clot, mingled with a little white fibrin connected with the fibrinous clot in the dilatation above the clavicle, but not attached to the fibrinous wall of the lower dilatation.

The clot in the dilatation above the clavicle extended across the calibre of the vessel, and prevented the flow of blood into the axillary vessel.

It should have been mentioned that the upper lobe of the lung was attached to the thoracic wall at the level of the seventh rib from the spine around to the sternum. In the thoracic aorta, atheromatous disease was very marked; the calibre of that vessel was irregularly dilated, and in parts the coats were quite thin. The other arteries, with the exception of the innominate and right subclavian, were normal. The cords of the brachial plexus of nerves were intimately connected with the upper portions of the tumor, and were pressed against the under-surface of the clavicle.

The subclavian vein was found stretched over the upper dilatation, and its calibre was so encroached upon that the return-blood was markedly obstructed.

The other organs were entirely normal.

Remarks.—The aneurism commenced in the second portion of the subclavian, and reached slightly into the third portion of the vessel. (This statement is made approximately, as the guiding-mark, the first rib, had disappeared.) The dilatation of the vessel was not uniform; the upper and the lower walls alone seem to have participated in the bulging.

The lower dilatation descended into the thorax, eroded the first and second ribs, and depressed the apex of the lung, becoming a *diffused* aneurism, after the manner described by Erichsen.

At the operation, therefore, it is probable that the aneurism had no true sac, but was bounded by the lung-tissue, pressed downwards from its normal position and condensed, and by the muscular tissues around the apex of the thoracic cavity.

The horse-hairs were thrust into this cavity, and their effect was good, resulting in a marked decrease of the pulsation and thrill felt below the clavicle,

although there was no decrease of the pulsation in the tumor above the clavicle.

It was not until the third day after the operation that the clot began to interfere markedly with the circulation, sufficiently to interrupt the radial pulse. After this day the tumor above the clavicle began to harden, through the extension of the clot from below upwards, and this coagulum barred quite completely the passage of the blood into the axillary vessel, but did not absolutely prevent its entrance, for it is recorded in the notes that the recumbent position slightly restored the radial pulse. Simultaneously with the hardening of the tumor above the clavicle, the return of venous blood from the arm was interfered with by pressure on the subclavian vein, which, at the autopsy, was found stretching over the anterior face of the upper dilatation.

Now, the formation of this clot, which only partially obstructed the vessel, and which from the position of the upper dilatation was connected with the clot in the lower opening only at its distal portion, directed the full force of the blood-current into the proximal portion of the lower opening against the new-formed clot, which, from its position, had no connection with the clot in the upper dilatation. The effect of this strong blood-current was to hollow out a new cavity in the site of the former aneurism. Inspection of the walls of the cavity shows this result very clearly, for on its walls are found a loop and two ends of hair protruding into the newly-formed cavity.

The formation of the clot in the lower sac was producing a cure of the aneurism, similar to results seen in the natural cures of sacculated aneurism, by the deposit of laminated clot in the sac, leaving a passage for the blood through the vessel behind it. If the sac had been well supported by firm tissue, and not, as was the case, been allowed to descend farther into the thoracic cavity by the receding lung, all might have been well, and a cure resulted.

It has been shown that there was no communication between the sac of the aneurism and the mass of dark clot found in the thoracic cavity. Whence, then, came this blood, and what force was it that compressed the lung and stripped the ribs of their covering, and pressed out the tissues in the axilla? The first cause that acted to compress the lung and denude the ribs was the sac of the aneurism; and this pressure must certainly have caused an adhesion to take place between the two pleural surfaces, and when the new cavity was formed in the laminated clot it again began to press down in the thoracic cavity, tearing apart the lung and pleura, stripping the ribs of their covering, and compressing the lung. The process of tearing the pleura lacerated the intercostal vessels, as they were found lacerated at the autopsy, thus supplying a source for hemorrhage,—hemorrhage that was not likely to cease, hemorrhage that was likely to be very gradual, but still of an increasing character, as each rib and its intercostal artery suffered in succession as they were found to have suffered. No hemorrhage from a ruptured aneurismal sac or from a lacerated lung would have been so slow in its progress, nor would

the force of an increasing accumulation of blood from either of these sources have been applied in such a manner as to push outwards the periosteum of the ribs and their intercostal muscles. The force must have proceeded from the line of ribs, and worked in both directions, compressing the lung one way, and pushing the tissues of the costal wall in the other direction.

The notes of the case show that the accumulation in the thoracic cavity was very gradual, that there was no rupture of the aneurismal sac and consequent sudden depression of the circulation, and that there was no sudden laceration of the lung with its attendant copious hæmoptysis.

The symptoms show a gradual compression of the lung, and that when the upper dilatation of the vessel hardened, and the clot obstructed completely the flow of blood into the axillary artery, an increasing fulness in the axillary and subclavicular region showed that the laminated clot in the aneurism was being forced downwards, and from that time a gradually increasing dulness of percussion was found posteriorly and laterally, corresponding to the position the blood occupied in the thoracic cavity.

And further, the tumor in the axilla was never a fluctuating mass during life; it was always tense, showing the great pressure the blood in the thoracic cavity was under, and the great force it was capable of exerting; after death, the axillary tumor was soft under pressure.

The stridulous breathing noted before death was undoubtedly caused by the pressure of the encroaching blood-mass narrowing the calibre of the bronchi, and possibly the trachea.

PAPILLOMATOUS GROWTHS IN THE LARYNX OF A CHILD.

Read before the Pathological Society of Philadelphia.

BY R. M. BERTOLET, M.D.

I AM indebted to Dr. Mears for this fine specimen of laryngeal papillomata. Unfortunately, we have only the left lateral half of the larynx and trachea to exhibit; the other half of the organ is said to have presented about the same development of the papillary excrescences. The vocal cord is entirely concealed, and the Morgagnian ventricle is nearly filled by these finely-fringed growths, which are also seen covering the ventricular band and extending down over the subglottic region. From such an extensive invasion, which must have almost completely filled up the glottic fissure, it is easy to surmise the symptoms of croup, aphonia, and dyspnoea that must have manifested themselves during life.

The only history obtainable in the case is to the following effect. A male child, 2½ years old, about three months ago became hoarse, and soon presented symptoms of croup, for which it was unsuccessfully treated by a young medical student, until death by asphyxia occurred. No laryngoscopic examination being made during life, no attempt to remove the growths was made. Trache-

otomy was not performed. It cannot be ascertained whether the child presented any evidences of hereditary syphilis: the father, however, is said to have marks of constitutional syphilis.

The microscopic appearance of this specimen does not differ from that ordinarily seen in these growths; most of the papillæ are covered with several layers of tessellated epithelium, but at some points a layer of long cylindrical cells is seen covering the entire papillæ. Ciliated epithelium, however, is not formed. These epithelial cells are supported upon a very thin column of connective tissue, with small blood-vessels in the centre of each papilla.

The aggregation of a number of these papillary growths forms the papillomatous tumors of the larynx, presenting the well-known cauliflower appearance. In this region these growths do not differ from those formed upon other situations of the mucous membranes; they closely resemble the hypertrophied papillæ of the cutaneous surface as met with in condyloma and verruca. They are by far the most frequent variety of tumors found in the larynx. Of one hundred growths in the larynx, Mackenzie found no less than sixty-seven belonging to this class. They have been observed much more frequently in the male than in the female. The vocal cords seem to be their seat of predilection. Papillomata of the larynx are also more apt to occur at an earlier period of life than the other varieties of neoplasms. In the forty-eight cases of congenital laryngeal growths and in those occurring during infancy collected by Dr. Causit, nearly all, when examined microscopically, were found to belong to the non-malignant papillomata.

This makes the third case of laryngeal growth occurring during childhood that I have as yet seen and had an opportunity of examining microscopically. One was exhibited by Dr. William Pepper to the Philadelphia Pathological Society in 1871. The other is an unpublished case, which I desire to report briefly in this connection, since its microscopical appearances so closely resemble those of the preceding case that one description and illustration will serve for both. It was also the first instance in which I resorted to the freezing process to induce local anæsthesia of the larynx. This method and its practicability, it will be recollected, were fully detailed at the last meeting of the Society, in connection with the removal of the tracheal growths then exhibited.

E. M., æt. 11 years, was referred to me by Dr. Pepper in November, 1871. One and a half years previously the boy first began to grow hoarse; this gradually increased until he was no longer able to speak above a whisper. Upon attempting to speak loud, he complains of a painful sensation in his throat. When quiet and resting, the patient's breathing is always noisy, accompanied with prolonged inspirations. It becomes more hurried and difficult after any active exertion. He is frequently aroused from his sleep with more or less pronounced dyspnoea.—"sitting upright and gasping for breath." The aphonia is so pronounced that he is unable to speak loud enough for his teacher at school. No marked general or local affection appears to have ushered in the hoarseness in this case; the mother and

attending physician imagining that the boy was merely suffering with a protracted cold.

The attacks of dyspnoea, accompanied with lividity of the features, also occur occasionally during the daytime. The mother states very positively that these paroxysms have very often appeared for several years prior to the commencement of the aphonia, thus pointing to a very early period at which the papillomata first made their appearance. The general health of the patient is undisturbed.

The laryngoscope showed the mucous membrane lining the epiglottis and larynx to be congested and of a deep-red color. The anterior third of the rima glottidis is filled up with a large, uneven mass of papillary growths, of a reddish-white color. They arise from the mucous membrane covering the parts inserted in the receding angle of the thyroid above the vocal cords; a second smaller mass was subsequently observed arising from the under surface of the left vocal cord, also near its point of insertion into the thyroid cartilage. The movements of these growths during forced respiration were very slight.

The larynx was found to be extremely irritable, so that a spasm of the ventricular bands and vocal cords would ensue whenever any instrument was introduced. This irritability was in a great degree overcome by frequently catheterizing the parts, yet not sufficiently to permit of the evulsion of the growths. Local anæsthesia by means of the chloroform and morphia pencillings, owing to the youthfulness of the patient, was not deemed advisable. The freezing process, however, was applied, and, after several ineffectual attempts, finally permitted the parts to be manipulated with the greatest freedom. At first the pain caused by the rhigolene was too great to be endured for any length of time. Subsequent applications were better borne. The growths were removed by means of the wire écraseur and the crushing laryngeal forceps of Mackenzie, and the points of attachment subsequently cauterized with solid nitrate of silver. The patient being very irregular in his attendance, the treatment extended over a period of nearly one year: he was dismissed as cured in October, 1872, a slight roughness only remaining to the voice. The patient would curiously titillate either of his ears; referring the pain to the ear corresponding to the side of the larynx which had been seized upon by the forceps. A number of trials were made of this curious phenomenon by many of my colleagues, in which the patient invariably referred the pain to the ear of the same side as that of the larynx touched. An intense ringing noise, lasting from one to two minutes, would be complained of in the ear, which the patient said was the reason for the insertion of his little finger into the external meatus.

ARE THE CONVULSIONS OF CARBOLIC ACID POISONING CEREBRAL OR SPINAL IN THEIR ORIGIN?

BY JOHN R. HAYNES, M.D.

IN Prof. H. C. Wood's recent work on Therapeutics is a highly interesting account of the physiological and therapeutic action of carbolic acid. It is shown that this agent in poisonous doses produces general convulsions; and, further, that the seat of these convulsions is undetermined, the French observer Labé maintaining that they originate in the brain, and the German Salkowski asserting with equal positiveness that their source is in the spinal cord. It might be supposed that no difficulty would exist in settling this question by

poisoning one of the lower animals with the drug and dividing the cord. If convulsions still occurred in the posterior limbs, no doubt would exist of their spinal origin, and *vice versa*.

Both the observers mentioned have thus experimented, and each has found the results to corroborate his views.

The following experiments were undertaken with a view to the determination of the question.

Experiment I.—The spinal cord of a cat was divided between the first and second dorsal vertebrae, and three drachms of liquefied carbolic acid were injected into the connective tissue. In fifteen minutes the muscles of the head, anterior extremities, and abdominal walls began to contract spasmodically, and soon well-developed clonic convulsions set in. The posterior extremities were moved slightly by the action of the abdominal muscles. The dorsal aspect of the cat remained perfectly quiescent. As soon as the convulsions became marked, the animal, which had remained in a semi-unconscious state after ether had been given to destroy the pain of the operation, was killed.

Experiment II.—Three drachms of liquefied carbolic acid were injected into the peritoneal cavity and subcutaneous connective tissue of a cat, after dividing the spinal cord between the fourth and fifth cervical vertebrae. In ten minutes the muscles of the face were convulsed, together with the diaphragm. The extremities remained motionless, except when excited by local irritation, when marked reflex movements occurred. The animal was killed in half an hour.

Experiment III.—Two drachms of liquefied carbolic acid were injected into the cellular tissue of a cat. Fifteen minutes afterwards convulsive movements of the head and extremities commenced, and continued to increase in strength. In half an hour another drachm of the acid was injected, and the convulsions grew still stronger. After a second interval of half an hour, an additional drachm of acid was injected, making half an ounce in all. The convulsions shortly became less marked in the posterior extremities, and then ceased. The anterior extremities moved more feebly than before, but did not become still until death, which happened three hours after the first injection.

From these experiments it is evident that the convulsions of carbolic acid poisoning are of cerebral origin. In experiments showing a contrary result, the spinal cord could not have been entirely divided.

THE TREATMENT OF EPISTAXIS.

BY ELLIOTT RICHARDSON, M.D.

HAVING read recently, in *The Dublin Journal of Medical Sciences* for November 1, 1873, a paper by Dr. Leeper, describing a simple method of arresting hemorrhage from the nose by the use of suppositories containing persulphate of iron, it occurred to me that it might be worth while to offer to the readers of the *Philadelphia Medical Times* a brief account of a somewhat similar procedure which I found very efficacious in a case of very obstinate and profuse bleeding from the nares, which came under my care when a resident in the Pennsylvania Hospital, during the winter of 1869-70. The patient was a negro woman, who had been subject to occasional attacks of epistaxis,

which had always yielded to the use of cold or other simple remedies.

When she came to the hospital she said she had been bleeding from the nose for several days; but as her appearance did not indicate extreme anæmia, and as the hemorrhage was promptly stopped by some simple application which I do not now recollect, and did not return within the hour which I directed her to wait, I was not inclined to credit her statement, and sent her home, with directions to return if epistaxis should again occur. In the course of three or four hours she returned, with the blood again flowing. She was now placed at perfect rest in bed, and the hemorrhage again checked, only, however, to return with increased profusion in about half an hour. After several remedies were employed unsuccessfully, I concluded to try a more continued application of styptic material to the bleeding surface. Two strips of lint were cut about an inch wide, and over one surface of each powdered persulphate of iron was sprinkled. Each strip was then rolled up, making a plug large enough to fit closely in the nostril, containing, within, the styptic powder, and leaving only the clean surface of lint to come in contact with the mucous membrane. One of these was placed well within each nostril, and retained in position, all clots having previously been removed. As successive portions of the rolls became moistened with blood, the persulphate was dissolved out, and speedily stopped the hemorrhage. The plugs were allowed to remain in for twelve to twenty-four hours, when they were removed without difficulty, and without the occurrence of further hemorrhage.

In the number of your journal for August 1, 1872, Dr. Curtin reports a somewhat similar method of using tannic acid, though, if I mistake not, he advises the tannic acid to be brought directly in contact with the mucous membrane.

The advantages of the method I have described are evident, since it enables the surgeon to place a repository of a powerful styptic near the seat of hemorrhage, without bringing it in direct contact with the mucous membrane, thus avoiding the superficial but annoying slough which always follows the direct application of dry persulphate of iron or a concentrated solution of it. It also furnishes an abundant supply of the material, which is dissolved out only as it is wanted by the bleeding vessels.

In cases where it will answer the desired purpose it is infinitely less difficult to apply, and less oppressive to the patient, than the plugging of the anterior and posterior nares,—an operation always disagreeable both to the patient and the surgeon. Dr. Leeper advises to combine with the local treatment free internal use of ergot.

CASE OF ASCITES CURED BY DIGITALIS.

BY W. S. MAXWELL, M.D.

LOUISA R., aged 36 (colored), had been suffering for several months with abdominal pain, suppressed menses, and general debility, with swelling of the abdomen. April 1, 1873, my father saw her with me.

The abdomen was greatly distended, and contained, I suppose, from three to four gallons of fluid. Bowels were constipated, breathing difficult, violent colics would ensue on eating the most simple things. Urine was scanty and high-colored, pulse quick and feeble. She was unable to lie down at all, owing to the difficulty of breathing.

Treatment.—Hydrargyri chloridum mite, gr. v, was ordered at bedtime, with potassii bitartras and jalap in the morning as a purge; this was continued for some time with good effects at first, but it soon ceased to do any good. Digitalis, squill, infusion of juniper-berries, and numerous other diuretics, were given, while the strength was supported by tonics, stimulants, and nutritious diet, but without avail.

June 1.—We saw her together again. The symptoms were growing worse. Tapping was suggested, but postponed for a while. Two grains hydrargyri chloridum mite with one-fourth grain of opium were ordered three times a day, and fifteen drops of tincture of digitalis every six hours. This course was persevered in for several weeks; the fluid was all eliminated by the kidneys.

At this time, March 2, 1874, the woman is enjoying good health.

TRANSLATIONS.

THE LOCAL TREATMENT OF CAVITIES IN THE LUNGS (Fr. Mosler: *Centralblatt für die Med. Wissenschaften*).—In the cases of two patients who had cavities in their lungs, lying near the surface, and of whose recoveries no hopes were entertained, Mosler performed the operation of paracentesis thoracis, and injected a dilute solution of the permanganate of potassa.

There was no reaction in consequence of the procedure, and the general symptoms of the patients were so much more favorable that he was encouraged to make a fistula directly into the lungs. The patient who was thus operated upon was a man aged 49 years, who had had a cavity in the upper lobe of the right lung for five years, and who was also suffering from amyloid degeneration of the kidney and intestine.

On the 2d of July, 1873, a perforation was made in the second intercostal space, five and a half centimetres to the right of the edge of the sternum, through the intercostal muscles and the pleura, and was continued into the cavity in the lung. Into the opening thus made a silver drainage-tube was inserted, through which there was a free discharge of pus, which was increased by coughing. The operation was not followed by fever, and the general condition of the patient was much improved. An attack of hæmoptysis occurred; for the relief of this, a diluted solution of the persulphate of iron was injected through the canula, with the happiest effect; and, later in the treatment, inhalations of atomized carbolic acid and tincture of iodine were made in the same way. The pus became more healthy, was less in amount, and the process in the lung seemed to be retarded in its progress; the patient, however, gradually sank, and died four months after the operation.

On account of the discharge of pus, which continued to the last, the introduction of carbolic acid through the canula was continued twice daily until the death of the patient.

At the autopsy, the two layers of the pleura were found to be adherent over the whole of the right lung, and on the upper lobe of the lung the change had gone on to the formation of a thick, white false-membrane, of an almost cartilaginous consistence. Through the anterior part of the other lobe there was a fistulous canal leading to a cavity filled with a yellow, creamy fluid,

which involved the greater part of the upper lobe. This cavity was lined partly with a smooth membrane, and partly with ridges upon the apices of which some feeble granulations were to be seen. The spleen, kidneys, and intestines were found in an advanced stage of amyloid degeneration. From the results of the treatment pursued in the case, Mosler concludes that the lungs are more tolerant of surgical interference than has been supposed. He thinks, too, that the method is of some value in rendering the symptoms less severe, and hopes that more careful experiments of a similar character will be made.

OPERATION FOR CANCER OF THE RECTUM BY MEANS OF THE GALVANIC CAUTERY.—Dr. Verneuil is said (*Gaz. Méd. de Paris*) to have performed recently the following operation for the relief of cancer of the rectum.

By aid of the galvanic knife, a horse-shoe incision was made, the convex portion of which was situated between the anus and the vulvar commissure, while the branches terminated on a level with the point of the coccyx.

These branches were united by a transverse incision a little behind the anus, and thus a flap was formed which might be called coccygeal, since it was detached from the deeper parts: it was held out of the way by an assistant. The various tissues being divided by delicate strokes of the galvanic knife, the isolation of the rectum from the vaginal walls was completed, and, the superior limits of the tumor being reached back of the rectum, the latter was divided longitudinally by the écraseur. By using the écraseur four times, the upper limits of the tumor were then separated, and the entire mass detached.

About two and three-eighths inches of the rectum were removed by this operation, which possesses the advantage of being performed without hemorrhage and allowing a full view of each step of the procedure. When last heard from, after several weeks, the patient was doing very well.

A. V. H.

CUTANEOUS DISEASE CAUSED BY THE BROMIDE OF POTASSIUM.—Dr. Neumann reports (*Wiener Med. Presse*) the case of a child æt. 5 months, suffering from a cutaneous eruption due to large doses of bromide of potash. The child had, in the course of a prolonged treatment for convulsions, taken sixteen scruples of the salt, and the eruption made its appearance after twelve scruples had been taken. Tubercles of a hemispherical shape, the size of a pea, upon the summits of some of which were crusts, were found on the body and the hairy scalp. After the removal of the crusts there could be pressed out a mass of sebaceous matter, colored yellow by the admixture of pus. On the forehead, and more especially on the skin of the cheeks, the spots of the eruption were larger. Upon the left cheek there was a spot about the size of a thaler, covered with dry crusts of a dark-brown color. Beneath these crusts were numerous protuberances of a warty character. The eruption was most marked on the lower extremities. In addition to the crusts described above, upon the leg there were seen also bullæ of various sizes, filled with a fluid of a yellowish tinge. A microscopic examination demonstrated marked changes in the upper part of the crusts, and also in the hair-follicles and in the sebaceous glands.

AMYLOID DEGENERATION OF CARTILAGE.—M. Hé-nocque (*Gazette Médicale*, February, 1874, p. 95) describes briefly amyloid degeneration of the bone-cartilages,—a degeneration whose possibility has previously been proven by Virchow and by Hagen.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 28, 1874.

EDITORIAL.

OUR ANNUAL OVERFLOW.

IN our editorial of last week we advanced the propositions that the medical colleges (as at present organized) are the enemies of the profession, and that the faculties are not to be blamed for this and are not to be expected to alter it. The deficiencies of our educational system are so generally admitted that they scarcely need any further illustration than that which we gave last week. In the various discussions upon the subject which we have listened to, however, we have never yet seen any one who was bold enough to tell the whole truth; and to-day, at the risk of incurring the curse which the Jewish Bible laid upon those who uncovered the nakedness of their parents, we propose to say some things which we believe the profession needs to look squarely and honestly in the face; for, in all earnestness, it seems to us that, in spite of the clamor, we are somewhat in the position of the man who dares not be honest to himself and place his deeds and his character at the judgment-seat of his own reason.

The theory of medical education at present is that the candidate studies a year and a half in the office of some practitioner, and then attends two courses of lectures before he graduates, making, in all, a term of three years. The fact is that a large proportion of the candidates really study only one year and a half, and some only one year. A farmer's son determines to be a doctor; forthwith he applies to the family physician, is dubbed a

medical student, and borrows a treatise by some ancient worthy,—a treatise which was, perhaps, the meat and the drink of his preceptor's student-life, thirty years before. So far, so good; but money is scarce, and through the long summer months the farmer utilizes his heir in the harvest-field, or more commonly the young man teaches the district school to gain the means which shall support him during the winter in the city. October finds him at the college. All winter long he labors, or loafs, as the case may be. The next spring he hies away to the country, to return again in the autumn; having, it may be, spent the summer precisely as the previous one, or else having gone over certain text-books very much in the sense of the boy who laid his book on the floor, stepped over it, and, in reply to his teacher's questions, vigorously asserted that he had been over his lesson three times. Often the last summer of a student's life is given to honest study, but often it is not; and it does not pass the power of human knowledge to know men who have graduated when they had done no real work until the last winter session. The knowledge which the examining board has as to the time during which the candidate has prosecuted his studies is often derived solely from the statements of the candidate himself, and from his having bought two sets of tickets. We know that at least sometimes untrue statements pass unchallenged: so that the man who has not, except on his thesis-paper, even pretended to study for more than a year and a half is recorded before the degree-conferring power as a three-years student. These things being so, it is evidently preposterous to claim that our graduates are students of three years' standing. What is the examination that tests the fitness of candidates thus prepared? Performed by men whose bread-and-butter depends upon the number that they let through,—performed by these men in secret, with no responsibility to any power but their own consciences,—performed with the knowledge, or at least with the belief, that if they do not dub the medical knight a rival organization will do it for him gladly,—performed under these circumstances, the examination cannot be anything other than it is, *i.e.*, an apology to public opinion, the last act of a farce before the tragedy commences.

If any one doubts these things, let him ask our army medical examining boards during the late war as to the deficiencies of many of the graduates of the most respectable schools; or let him ask coaches, or, as they are commonly called, "quizzers," and, our word for it, he can find men who have had hundreds of students, good, indifferent, and bad, who will testify that they have graduated num-

bers of ignoramuses, and have lost scarcely one per cent. of the applicants. If there be yet a doubting Thomas, let him get the private confidence of some consultant, and find the fruits of this annual sowing.

How can a profession be honored that sells its birthright for a mess of pottage? How can any body of men be distinguished as a whole, when a few hundred dollars and a few months' work give admission to the ranks? It is hard to tell whether to laugh or to cry over the solemn farces of Commencement-Day; but assuredly the spectacle of grave critics searching assiduously for the causes of the profession's low estate, when the mud of the quagmire is upon their very persons, is most laughable.

Unless these critics are the blindest leaders of the blind, they must be hugging delusions that they may hide that which they are afraid to see and may quiet the fancies of uneasy consciences. The marvel is not that we have so little, but that we have so much, of public confidence. The reason that we are still looked upon with a measure of esteem is that there are numbers of medical students who feel deeply the responsibilities of their position, and avail themselves of the opportunities offered to become really educated physicians; the fault of the colleges being not that they do not afford sufficient opportunity to those desirous of eminence, but that they do not require the student to prepare himself thoroughly before granting him a diploma.

We had fully expected to discuss our second proposition in the present editorial, but our pen has run away with us, and, the allotted space being already filled, our final words must be postponed for another week.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, FEBRUARY 12, 1874.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

DR. JOSEPH G. RICHARDSON presented, for Dr. A. FRICKE, the specimens from a case of *general tuberculosis with enlarged lymphatics* from a German girl aged 21 years, admitted into the German Hospital on November 17, 1873. The principal symptoms upon admission were slight cough, headache, pain in the lumbar region and also upon the inner side of the limbs. Her own expression was that she felt tired, and only wished to get into bed. Her clothing was wet; her feet were very cold and wet. The most noticeable feature was great enlargement of the cervical glands. The lymphatics in other portions of the body were also enlarged, as was found upon subsequent examination.

At the very first, symptoms of a typhoid character began to manifest themselves. During the second twenty-four hours after her admission she gradually became unconscious. No food, however, liquid or concentrated, would she swallow. This condition continued, gradually becoming more grave, until she died on November 27, 1873, ten days after admission.

A *post-mortem* examination was made; it was found that all or nearly all of the organs were more or less infiltrated with tubercles. There were evidences of violent inflammation of the brain: tuberculous deposit at the base, and considerable exudation into the ventricles. The lungs were studded with small abscesses. The liver was affected also, as was the spleen. The mesenteric glands were greatly enlarged; also, the deep lymphatics of the abdomen and pelvis.

Dr. H. LENOX HODGE exhibited an *ovarian tumor*, removed by Dr. Agnew. The patient was 33 years of age, married, and the mother of two children. The tumor was first noticed in January, 1873; since then it had steadily increased in size. She was tapped in December, and again in January. The tumor is multi-lobular, and weighed eighteen pounds, solid and fluid. The microscopical examination has been made by Dr. Richardson.

Dr. JOSEPH G. RICHARDSON said he had recently made some examinations of ovarian fluid with a view to determine the presence of the so-called *ovarian cell* of Dr. Drysdale, and that in some six examinations which he had made he had invariably discovered it.

Dr. JAMES TYSON said he thought the way to settle the question was to examine, not ovarian fluid, in which the cell undoubtedly existed, but fluids from other sources, with the view of determining the possibility of its occurrence elsewhere.

Dr. T. desired also to say that in the discussions into which he had entered during the past year upon this subject, and in which he had taken decided ground against the existence of any peculiar ovarian cell, the idea he had entertained of the characters of the cell referred to by Dr. Drysdale was erroneous. He had thought Dr. Drysdale alluded to the ordinary compound granular cell or exudation corpuscle of Gluge; but only recently, from the paper which Dr. Drysdale had kindly sent him, he had learned that the cell resembled more in size and characters the *leucocyte* in a state of fatty degeneration, and he had not as yet made any comparative observations to determine the presence of this body in other than ovarian tumor.

Dr. RICHARDSON remarked that if it could be proved that the leucocyte exhibited characters in its degeneration which were peculiar to ovarian fluid as contrasted with other abdominal liquids, it would still serve to detect such fluid, and might with propriety be called an "ovarian cell."

Dr. HODGE said there was one point in connection with this ovarian cell which he thought had not been alluded to even by Dr. Drysdale,—that is, as to whether it was found only in ovarian fluid, or in the semi-liquid gelatinous and solid matter of which ovarian tumors are also made up.

Dr. BERTOLET said he had not a clear idea of what was comprised by the term "*leucocytes*," and desired much to know its limitations.

Dr. TYSON replied that, after other better-known histologists, he had always used the word *leucocyte* in a generic sense, as including all that class of small, round, variously granular cells which, according to the situations in which they were found, were variously called white blood-corpuscles, mucus-corpuscles, young pus-corpuscles, or the round cells of connective tissue,—in other words, *dead amœboid cells*.

Dr. BERTOLET said he thought this was an error, in which theory had been allowed to supplant practice;

that the white corpuscle and pus-corpuscle were not the same.

Dr. RICHARDSON said the word leucocyte had been originally introduced by Charles Robin, who applied it to the class of bodies named by Dr. Tyson, whether alive or dead, as well as to exudation-corpuscles, and he believed also, provisionally, salivary corpuscles. He thought that if any one would treat white corpuscles contained in a drop of blood from his finger, first with water by introducing a small quantity at the edge of the thin glass cover, and then with weak aniline solution, in the manner described in his report on the white blood-corpuscle (*Am. Med. Assoc. Trans.*, 1872), he would have no difficulty in finding many globules which exhibited two or three, and occasionally those which displayed four or five, well-formed and strongly-tinted nuclei, and which manifested a precise identity, in that respect at least, with the leucocytes of pus, as described by older pathologists. By this experiment it was easily demonstrated that the characteristic formerly so much relied upon for the recognition of the pus-cell, and quoted by Dr. Bertolet,—namely, that it possessed two, three, or more nuclei,—was valueless as a means for its discrimination from the leucocytes of blood.

Dr. TYSON admitted that pus-corpuscles soon became very granular from fatty degeneration, and then presented objects which did not so closely resemble the white blood-corpuscle; but in their young state he did not think they could be distinguished, and to acetic acid and water both responded identically.

Dr. RICHARDSON said that about one white corpuscle out of thirty is ordinarily more granular than its companions, and he was strongly inclined to think that these white corpuscles were also the seat of fatty degeneration.

The PRESIDENT said it was very important to have clear ideas as to the exact application of terms. He presumed, of course, that this discussion referred simply to the morphology, and not the vital properties or developmental tendencies, of the cells in question. He said that he himself had been called upon to study cases where inflammation had obliterated the trunks of vessels,—a matter which brought up directly the question of being able to distinguish between the corpuscles in the surrounding inflamed tissue and the white corpuscles which remained in the softened clots. By no means which were available could he distinguish between the two.

Dr. RICHARDSON thought the more he studied the subject in connection with Cohnheim's observations, the more he was led to conclude that living leucocytes of pus and blood were identical physiologically as well as morphologically.

Dr. MORRIS LONGSTRETH exhibited the *specimens from Dr. Levis's case of aneurism of the subclavian artery*, treated by the introduction of horse-hair. (See Original Communication in current number of the *Medical Times*.)

Dr. HUTCHINSON said that he had examined the patient, both before and after the operation. There was a pulsating tumor above the clavicle, and another below it. Some of those who saw the case believed that the latter was situated entirely outside the chest-walls; while others thought it was due to the protrusion of an intra-thoracic aneurism. He had himself held the former opinion, because he thought he could feel the ribs passing beneath the tumor, into which the axillary artery could be traced. The autopsy showed that he was wrong, but it also demonstrated that the view that the aneurism had begun within the chest was also incorrect.

Dr. JOHN ASHHURST, Jr., remarked that an interesting fact revealed by the post-mortem examination was

the existence of *two* aneurisms, one arising from the upper surface of the vessel and extending above the clavicle, and the other originating on the lower surface and passing downwards into the chest, eroding the ribs, and finally making its appearance anteriorly. This condition does not appear to have been suspected before death, and the specimen thus furnishes an illustration of the frequent impossibility, in cases of internal aneurism, of making a positive diagnosis.

Dr. HUTCHINSON said there was no question but that the aneurism became more diffuse after the introduction of the horse-hairs. He had examined it after the operation, and there was an immense increase, while the aneurism above the clavicle very early became solid, and no expansive pulsations could be felt after a few days.

The PRESIDENT asked Dr. Hutchinson in what the rapid increase of the aneurism after the operation revealed itself, whether by extension of the area of dulness in the infra-clavicular region, or otherwise.

Dr. HUTCHINSON said he did not know what changes occurred in the first week, but that after the operation the dulness had extended very rapidly to the third, and probably to the fourth, rib. There was also posteriorly a corresponding extension of dulness, and there was bloody expectoration. He thought these symptoms might have been due to a low form of inflammation set up about the sac.

The PRESIDENT asked to how great an extent could the coats of the aorta be traced into the aneurismal cavity.

Dr. LONGSTRETH said he and Dr. Meigs had made a very careful examination, with a view of tracing the sac, and found none within the border of that cavity; within half an inch of where the aneurism gave way, there was no trace of anything but clot.

Dr. R. M. BERTOLET presented, for Dr. J. EWING MEARS, a portion of the *larynx of a child two and a half years old, filled with papillomata*. The child was healthy until two months ago, when there appeared symptoms of croup, which continued until death. It was born of syphilitic parents. The case is published in the current number of the *Times*.

Dr. JAMES TYSON presented a specimen of *intussusception* of the small intestine into the large, through the ileo-cæcal valve, from an infant boy seven months old. On Sunday, January 24, the child was remarkably bright, playing and romping with his father to an extreme degree. On the following day he had several discharges of blood, but no other matter, from the bowels, and towards evening vomiting set in. In the evening Dr. T. saw him, and, suspecting the condition at once, directed a dose of oil, followed by small doses of calomel (one-sixth gr. every hour). On the following day injections were ordered, and the calomel continued, to no purpose. On Wednesday the vomiting almost ceased, but the bowels remained unopened, and there was distinct dulness in the right iliac region. The vomiting returned the following day, there was more discharge of blood from the bowels, and the child died at 4 P.M. on the 29th, having had quite a normal stool immediately before death.

The *post-mortem* examination was made the next day. The abdomen, which was never markedly tympanitic, contained a large amount of fetid sero-sanguinolent fluid. There were peritonitis, and intense injection of the bowel throughout almost its entire extent, and the tumor presented was found at the seat of the ileo-cæcal valve. It was three inches in diameter, and a portion of intensely congested small intestine had passed through the orifice and formed the tumor.

Dr. TYSON also exhibited a *gall-stone* three-eighths of an inch in diameter, a nearly perfect octahedron, with somewhat irregular facets, passed by an unmarried

female about 30 years of age. She was jaundiced, her urine was loaded with bile, and she had the usual pain of biliary colic, which was somewhat intermittent, being worse at night. After an unusually severe attack the stools were examined, this stone found, and she rapidly recovered.

REVIEWS AND BOOK NOTICES.

ON DISEASES OF THE CHEST; BEING CONTRIBUTIONS TO THEIR CLINICAL HISTORY, PATHOLOGY, AND TREATMENT. By A. T. H. WATERS, M.D., Fellow of the Royal College of Physicians of London; Physician to the Royal Infirmary, etc., etc., Liverpool. Second Edition, Revised and Enlarged. Philadelphia, Lindsay & Blakiston, 1874. Pp. 431.

In this work, the first edition of which, forming a book of little more than half the size of the present volume, made its appearance in 1868, the author's object has been, as he states, to depict disease as found at the bedside, and to illustrate the application of therapeutics to thoracic affections by details of cases, without attempting to furnish a systematic treatise on diseases of the chest. It constitutes one of those valuable records of careful observation, made by a man of sound judgment and ripe experience in that best of all fields for correct medical investigation, a well-appointed hospital,—records which have for centuries formed the most substantial basis for the science of medicine. Some such harvest as this is, we believe, due to the profession from every man who enjoys the advantages of a hospital appointment; and, indeed, in those cases when year after year less fortunately-placed physicians come seeking fruit and finding none, we see no reason why the doom of the barren fig-tree should not be pronounced.

Dr. Waters first offers some observations upon the anatomy of the lung, in regard to the epithelium of the air-vesicles, on which point he differs from most modern authorities, including Rindfleisch and Franz Schulze; he then proceeds to consider the different forms and characteristics of pneumonia, in seven chapters, being the substance of nine clinical lectures; emphysema, in six chapters; and, more briefly, pleurisy, phthisis, hay-asthma, asphyxia, pericarditis, valvular disease of the heart, and thoracic aneurism.

Since it is manifestly impossible to furnish our readers with abstracts of these various lectures within the limits of this present notice, we will confine ourselves to a short *résumé* of our author's remarks upon the use of chloral hydrate in certain diseases of the chest. In the first place, Dr. Waters has found this drug "very valuable" in bronchitis, especially when complicated with emphysema, and when opium, if administered in quantities sufficient to produce sleep, might prove fatal. In such cases, from twenty to thirty grains of chloral have proved both efficient and safe as a hypnotic; whilst, to allay cough, five-grain doses of the same drug have sufficed. Our author has found chloral useful in procuring sleep in cases of asthma, both of the purely spasmodic kind and of that form complicated with emphysema; and has likewise employed it with great advantage in cases of phthisis pulmonalis and of disease of the heart, including both the fatty degeneration and valvular affections of the latter organ.

Dr. Waters mentions a few cases where distressing excitement or prolonged stupor followed the exhibition of chloral, and cautions us against its use in patients who are in the habit of smoking much and of drinking freely; also against continuing it for a long time, lest it enfeeble the circulation. He recommends that it should be administered in tincture of orange-peel or syrup of

Tolu, well diluted with an aromatic water; the dose being given after the patient is in bed and quite ready to compose himself for sleep, since walking about, or even crossing a room, after swallowing the mixture, will often bring on vomiting.

I. G. R.

A TREATISE ON THE DISEASES OF THE EYE. By J. SOELBERG WELLS, F.R.C.S. Second American, from the Third English Edition. Pp. 800. Philadelphia, H. C. Lea, 1873.

TREATISE ON THE DISEASES OF THE EYE. By Dr. CARL STELLWAG VON CARION, Professor of Ophthalmology in the Imperial Royal University of Vienna. Translated from the Fourth German Edition by Drs. D. J. ST. JOHN ROOSA, CHARLES S. GULL, and CHARLES E. HACKLEY. Pp. 171. W. Wood & Co., New York, 1873.

The prompt appearance of new editions of these standard works on diseases of the eye may fairly be taken as an index of the growing importance of this specialty, and of its appreciation by the profession at large. Owing to the diligence of the authors, and the care of the American editors, they represent fairly all our accurate and firmly-established information on the subject. The new methods of operation for cataract (Liebreich, Le Brun, Streatfield) are described but not criticised, the writers preferring, apparently, to wait for the slow but accurate appreciation of them gained by their application in a long series of cases. In both books the valuable researches of Schwalke, Schmidt, and Manz, demonstrating the lymphatic circulation in the eyeball and optic nerve, and the important rôle which it at times plays in the production of choked disk and inflammation of the optic nerve, have received due attention. The chapters on Diseases of the Retina and the Optic Nerve, treating, as they do, of the changes manifested in these organs in diseases of the nervous system, as also of those which are local manifestations of general diseases or lesions of particular organs, *e.g.*, those occurring in syphilis, leucæmia, diabetes, in Bright's disease, cerebral tumors, meningitis, etc., will be read with especial interest by the general practitioner. We are glad to see that the translators of Stellwag have insisted so strongly on the advantages obtained in ophthalmoscopic examination by the use of the upright image, which, owing to its magnifying the image of the fundus more strongly, enables us to see much more readily those minute changes which, in the use of the inverted image, owing to its smaller size and to the flood of light, are apt to escape our attention. Moreover, we can, in the direct method, employ the plane mirror and a comparatively feeble light, and thus render the examination far less annoying to the patient. The ophthalmoscopic plates appended to Stellwag are not so good as those in the earlier German editions; and those in Wells, taken from Liebreich's atlas, are less accurate than the originals.

W. F. N.

DICTIONARY OF ELEVATIONS, AND CLIMATIC REGISTER OF THE UNITED STATES. By J. M. TONER, M.D. New York, D. Van Nostrand, 1874.

This little book, or overgrown pamphlet, of 100 pages, is evidently the result of a great deal of work and research upon the part of its author, and must be of great use as a book of reference to all students of the climatology of this great country. It contains, in addition to elevations, the latitude, mean annual temperature, and total annual rain-fall of all the cities, towns, and localities in the United States concerning which the requisite data have been obtainable. The orographic and other physical peculiarities of North America have also been noted with great care. The list of localities seems to be very full; but either our geography is at fault, or else the author is one of those sanguine and patriotic mortals who believe that this

great Yankee nation is to gorge the universe, and that the eagle of freedom is to screech from all the world's mountain-tops. We judge this because we find included in this list of elevations of the United States localities in Egypt, the Himalaya Mountains, Australia, South America, Europe, etc., etc. Of course this faith of the author in the nation of his forefathers does not lessen but enhances the value of the book, which we highly commend as a work of reference to all interested in the subject.

LA VIE: PHYSIOLOGIE HUMAINE APPLIQUÉE À L'HYGIÈNE ET LA MÉDECINE. Par le DR. GUSTAVE LE BON. Paris, J. Rothschild, 1874.

This book contains within its muslin covers a little over nine hundred pages of large type, and therefore does not afford room for a complete discussion of the great science of physiology. Indeed, we do not think the author of the work would claim any such position for his bantling, but would be well satisfied with the acknowledgment that it is a clear, well-written, and easily-read book, of such character as is wanted by the student of medicine; stating briefly and dogmatically well-established facts, and leaving to the future all the doubtful problems. As its name indicates, it is a treatise upon what we know in this country as the "institutes of medicine" rather than upon pure physiology. Thus, in the chapter upon blood, transfusion is discussed at considerable length, whilst the subject of the origin of blood is dismissed in a few words; and in the chapter upon the eye, such topics as the hygiene of myopia, and the choice of glasses, have found entrance.

A prominent feature of the book is the illustrations, of which there are three hundred and thirty-nine woodcuts: some of them quite striking, nearly all of them very good. It appears in some places as though an anatomical work had been emptied into the treatise, as we have page after page of cuts which are purely anatomical, representing bones, muscles, nerves, arteries, or viscera, as the case may be. In a student's book these illustrations are in place, but we opine that practitioners would prefer the space occupied by discussions of some of the questions which are imperfectly considered, seemingly from want of space.

GLEANINGS FROM OUR EXCHANGES.

DISLOCATION OF THE SPINE—REDUCTION.—The following case, reported by Dr. L. W. Bliss, is taken from the *Transactions of the Michigan Medical Society*:

A man, aged 41 years, was superintending the raising of a stick of timber, under which he had his shoulder, when it fell, carrying him beneath it, forcing his breast forward upon his knees, dislocating the spine at the eleventh dorsal vertebra, and fracturing the ninth, tenth, and eleventh ribs at their surgical neck, and the spinous process of the eleventh dorsal vertebra. He was removed from beneath the timber in an almost insensible condition, from which he recovered in about one-half hour, with complete paralysis of that portion of the body below the dislocation. An attempt was made to replace the vertebra by pressure, which failed, and extension and counter-extension were followed by a similar result. The surgeon then knelt upon the floor, and, stationing assistants at both extremities of the patient, he directed the body to be forcibly flexed over his knees as a fulcrum, while one hand was placed upon the dislocated part. In this manner, a reduction was effected, the spine resuming its natural appearance when the body was extended. In three minutes after the reduction the patient was

able to move his feet, and sensibility returned, while the power of motion was recovered in half an hour. With the exception of retention of urine, lasting three days, no untoward symptom supervened. The patient was confined to bed for seven weeks, and availed himself of the assistance of crutches for five months.—*Boston Medical and Surgical Journal*.

BROMO-HYPERIDROSIS OF THE FEET (*Irish Hospital Gazette*, February 16, 1874).—Mr. Maturin reports the case of a girl, æt. 16, who was affected in the following manner by the use of a pair of slippers having vulcanized india-rubber soles with cloth uppers, the india-rubber covering the cloth over the toes, the posterior aspects of the heels, and a margin about half an inch broad along the sides. After wearing them a few days her feet became cold and white during the day, and perspired profusely; shortly after going to bed they grew red and swollen, with a burning, prickling sensation. In the next fortnight the perspiration increased, and the feet became excessively tender; and a week later, the slippers having been discarded, she applied for treatment. The soles and sides of her feet were white and sodden, extremely sensitive, and were covered with an offensive perspiration. The upper surfaces of the toes were slightly affected,—the diseased portion corresponding exactly to that covered by the india-rubber on the slippers. The patient was feverish, and had no appetite. She was ordered quinia in five-grain doses, low diet, and perfect rest. The next day her fever was less; the feet, however, were hot, the affected portions being of a bright-red color, and so tender around the margins, where the epidermis was thin, that she could not bear to have them touched. The odor and perspiration were both excessive. The quinine was continued, and she was given $\frac{1}{100}$ gr. of atropia every three hours. All the symptoms soon abated in severity under this treatment. She was kept moderately atropized for about five days, when she was entirely restored to health. The india-rubber in her slippers was carefully analyzed, but no deleterious impurities were discovered. The supposition is, therefore, that the disease originated simply from the irritation of the accumulated products of decomposed skin-excretions.

GALVANO-CAUTERY IN TRACHEOTOMY (*Le Mouvement Medical*, January 10, 1874).—M. Krishaber reports two cases of tracheotomy. The first was in a man æt. 45, affected with vegetations seated in the trachea and the subglottic portion of the larynx, and occupying almost entirely the superior part of the respiratory canal. The operation was performed with the galvanic knife, and the sections were made slowly and carefully; all flow of blood ceased at once on touching with the knife the artery which produced it, and this was also the case in a profuse secondary hemorrhage, which took place some hours after the operation.

The other patient was a man, æt. 63, with a laryngeal tumor which was causing more and more intense aphonia and dyspnoea, and thus rendered asphyxia imminent and tracheotomy inevitable. The operation was conducted in the same manner, but the hemorrhage necessitated the application of a ligature, and the tracheal opening had to be made with a bistoury. M. Krishaber, while admitting the hæmostatic power of the galvanic knife, believes that the ligature and bistoury are still preferable, as offering more security against secondary hemorrhage.

CEREBRO-SPINAL ARACHNITIS (*The Irish Hospital Gazette*, January 1, 1874).—At a meeting of the Pathological Society of Dublin, Dr. Grimshaw reported the case of a young man, æt. 23, who was suddenly seized

with vomiting, faintness, and pain of head and back. He rapidly developed the symptoms of acute cerebro-spinal arachnitis, and died at the end of five days during the supervention of a convulsion. There were no spasms until immediately before death; no purpuric spots were noticed before death; the pulse never had the characteristic jerk so often observed; there was no hyperæsthesia. The post-mortem examination revealed slight softening of a small space of the upper portion of the spinal cord, and a thin layer of subarachnoid lymph effused over its cervical region; hyperæmia of the sinuses and veins, and deposition of yellowish lymph for a limited space over the parts at the base of the brain.

MORBID ANATOMY OF SCARLET FEVER (*Irish Hospital Gazette*, February 16, 1874).—Dr. A. W. Foot, at a meeting of the Dublin Pathological Society, presented specimens, taken from children æt. 7 and 12 years, who had died, one on the fourth, the other on the third day, of an attack of scarlet fever.

In both cases the solitary follicles were universally enlarged throughout the small intestines, but especially in the first and last portions of the bowel, and there was a corresponding tumefaction of the mesenteric glands. The agminated follicles were morbidly prominent and distinct in the elder child, who appeared to have died from the consequences of mechanical dyspnoea, and in whom there had been a profuse pharyngeal catarrh, with pulmonary œdema. The tonsils were found to be in a condition of "necrosis," containing masses of dead tissue in the form of shreddy sloughs.

In neither of the cases were the renal organs abnormal in size or weight, and their vascularity was but slightly increased.

EXTERNAL APPLICATION OF CHLORAL (*L'Union Pharmaceutique*, January, 1874).—M. Martineau has derived great advantage from the topical employment of solutions of chloral. In the bed-sores of typhoid fever he uses an aqueous solution of the strength of one per cent., first washing the sore well, and then covering it with lint soaked in this liquid. He says its effect is remarkable: the sloughing, atonic region taking on a healthy aspect, granulating, discharging less, and proceeding rapidly to a cure. When there is offensive suppuration he uses a mixture of chloral and eucalyptus.

MISCELLANY.

EAU DE COLOGNE.—

"BOSTON, February 14, 1874.

"MESSRS. EDITORS,—The other day, while looking through the medical pamphlets preserved in our City Library, I came across an advertising circular entitled '*Vertus et Effets de l'excellente Eau admirable, ou Eau de Cologne*, approuvée par la Faculté de Médecine, le 13 Janvier, 1727;' from this I learned what was quite novel to me—that eau de Cologne was originally concocted for a quack medicine. In the circular, which in type, paper, and language bears evidence of belonging to the last century, it is stated that this water was invented by an Italian, Sig. Paul Feminis, an old distiller of Cologne.

"It is described as a 'volatile spirit, extracted from the rarest and most delicate simples; an elixir which has the power of restoring the parts of the body that are attacked by any disease, or predisposition to the

same, of fortifying and re-establishing their natural functions, of insinuating into them a moderate and living warmth, which, sympathizing with their own, reanimates their vital forces, aids the coctions, and forcibly expels all the excrements.'

"The sheet ends with the usual

"'Caution.

"'It is undisputed that the Sr. Paul Feminis, inventor and author of the Eau admirable de Cologne, before dying, left his secret and the composition solely to Jean Antoine Farina, who notifies and cautions the public that Eau de Cologne, which is made and sold under any other name whatsoever, is neither of the quality nor the composition of that invented by the originator. The present owner, therefore, as the sole successor and inheritor of the said secret, making the only veritable Eau de Cologne, gives notice besides that every other brand is wanting in the good effects pertaining to that of the above said author, whose successor is Jean Antoine Farina, distiller at the sign of the City of Milan, Golden Scales Street, Cologne.'

"Yours very truly,

"JAMES R. CHADWICK, M.D."

—*Boston Medical and Surgical Journal*.

CELEBRATION OF ROKITANSKY'S BIRTHDAY.—The seventieth anniversary of the birthday of this distinguished pathologist was celebrated with appropriate ceremonies in Vienna on the 19th of February of this year. Delegations from all parts of the Austrian Empire, and also from many foreign lands, were present and took part in the festivities, and good wishes were sent by post and telegraph from numerous societies and eminent individuals who were unable to be personally represented. Long before the time appointed for the exercises to begin, the hall appropriated to the purpose was crowded by men whose names are of world-wide renown in science and literature, and who hastened to do homage to the distinguished professor. Prof. Langee delivered an oration, narrating the various services which Rokitansky has rendered towards the advancement of science, and, at the close of his address, unveiled a bust which his pupils had had made as a testimony of their earnest wish to hand down to posterity the features of one whom they so heartily revered. Numerous other addresses were made, and forty deputations presented their congratulations. In the evening there was a torch-light procession by the students of the various faculties of the University, from the Parliament House to the "Kursalon" in the "Stadt-park," where they were received by Rokitansky. Forming a circle around the building, they sang the "Gaudeamus," then resumed their march and extinguished their torches, and the birthday celebration was over.

NEVADA SODA.—A small lake in Churchill County, Nevada, covering an area of seven acres, is a perfect well of carbonate of soda in its almost pure state. Twenty thousand tons a year can be obtained from it. It is pronounced by chemists equal to the European soda.—*Druggist's Circular*.

THE Jardin d'Acclimatation at Paris recently received a medusa polyp, which on the day after its entry into the pool assigned to it had created a void around it and skilfully got rid of all its neighbors. This was a mystery until the water of the pool was analyzed: the water was found to be converted into a solution of vinegar, and it was apparent that it was one of those very rare molluscs, the vinegar polyp, whose body when plunged into pure water gives presently a strongly characterized acetic solution. The working of this animal is very curious; it produces alcohol, which it transforms into vinegar. The poisonous mollusc was, of course, quickly withdrawn, and placed in clarified vinegar in a closed jar, where it will pursue undisturbed the economical manufacture of the acid.

CAUTION TO DRUGGISTS.—A mixture of chromic acid and glycerin is a formula which has recently been highly recommended in certain affections of the mouth, scrofula, etc. Dr. Mascarel takes occasion to warn druggists that when these two substances are vigorously rubbed up together the result is a lively *explosion*, an accident which can be averted by adding the glycerin drop by drop, and grinding slowly.—*Il Raccogliore Medico*, No. xxxi., 1873.—*Boston Medical and Surgical Journal*.

DR. BALLE presented the other day to the Faculté de Médecine a young girl aged fourteen, named Blanche Dumas, from Issoudun, whose body, from the waist downwards, is double,—the two parts acting independently of each other. The two legs she uses for walking belong each to a different trunk, while a third one is quite insensible to pain. Her health is good.—*London Lancet*.

AFTER a prolonged debate, the Obstetrical Society of London have decided, by an overwhelming vote, that their by-laws did not allow of the admission of women as members. This interpretation of the by-laws seems to have resulted from the feeling expressed by several speakers that the admission of women would be ruinous to the Society.

THE death of Dr. Ernst Bock, pathologist to the General Hospital at Munich, in the 65th year of his age, is announced. He was the author of several works upon simple and pathological anatomy, but is specially known in Germany by his "Buch vom gesunden und kranken Menschen," and numerous other popular writings.

THE *Chicago Post and Mail* gives the following as the immediate cost of a first-class baby: physician, \$50; midwife, \$25; wet-nurse, \$50; dry-nurse (one year), \$150; clothing, \$200; baby-carriage, \$25; total, \$500.—*The Clinic*.

THE *London Lancet* deems the introduction of Pullman palace cars into England of sufficient importance to receive an editorial notice.

THE Worcester Press thinks that an *Eng* raving would most appropriately represent the scene of Chang's death.

THERE was a certain Pope who lost his physician, and to all who applied for the office he put the question, "How many have you killed?" Each doctor in turn solemnly asseverated that he had never killed any one. An old fellow, with a big beard, came at last. "How many have you killed?" asked the Pope. "*Tot quot*," said the old fellow, pulling his beard with both hands. The Pope was pleased with the confession, and, believing that he must at least be a man with an enormous experience, took him as his physician.

USE OF GLAZIER'S PUTTY IN SURGERY.—Ordinary mixed putty has been found by Mr. Courvall to be the softest and most applicable means of treating excrescences or tumors of various kinds where compression is desired, as it moulds itself so neatly to the skin. He believes it to be superior to dextrine, silicate of soda, or plaster bandages. It is a cheap and always attainable material.—*The Medical Press and Circular*.

THE motto for the successful essay for the Merritt cash prize, awarded by the New York State Medical Association, probably had more of truth than poetry in it. It was "Die Hoffnung eines armen bedürftigen Teufel,"—The hope of a poor needy devil.

PROF. ROKITANSKY is stated to have four sons, two of them—Karl and Prokop—rising young physicians and "Universitäts-docenten," one, Hans, a basso of the Imperial Opera at Vienna, and Victor a teacher of vocal music.

DR. WILSON FOX has been appointed Physician-in-Ordinary to their Royal Highnesses the Duke and Duchess of Edinburgh, the much-talked-of bridal pair.—*Boston Medical and Surgical Journal*.

THE London Dental Hospital has recently occupied its new building, and seems to be entering upon a career of renewed usefulness.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—Allow me a short space in your journal in reply to Messrs. X and Ex.

X may be dismissed in a very few words. Unable to cope with the *matter* of my communication, he has attacked the *manner*. His elegant Lord Dundrearyship's nostrils seem to be much disgusted at my want of "suave manners and courtly language," and he very consistently makes the asinine assertion that, if the dispensary-doctors do serve for nothing, it is for nothing "*save for self-interest*."

In marked contrast are the courtesy and convincing arguments of Ex. I did not mean to assert that hospitals and such-like institutions were destined to crush not only the struggling practitioner but to embarrass the whole medical profession, but intended to denounce their indiscriminate advice and their services to any who may demand them without question. Surely there are enough *deserving* poor in such a large city from whom to gain experience (for self-interest), without taking in those "of low degree" who may be able to pay but desire to shirk an honorable responsibility.

I cheerfully accord the high ability and great services of hospital-doctors, but am not on that account willing to allow them privileges not accorded to the humblest member of the profession. I readily assent to the usefulness and great charity of the institutions themselves when properly administered, but not that they shall be vehicles for the advancement of a few for their own selfish interests, and thus prove themselves like the fabled dog in the manger, allowing no one else to be partaker of the feast.

VERTEX.

SATURDAY, APRIL 4, 1874.

ORIGINAL COMMUNICATIONS.

FETID CORYZA.

BY J. SOLIS COHEN, M.D.,

Lecturer on Laryngoscopy and Diseases of the Throat and Chest, in Jefferson Medical College.

THE term *fetid coryza* appears to me better adapted than *ozæna* to designate the condition under consideration, though merely indicating a combination of characteristic symptoms—*discharge and odor*—attending disease involving the nasal passages, without defining its nature.

Fetid coryza is produced by various affections. It may be due to ulceration of the mucous membrane of the nasal passages or of the sinuses communicating with them, whether erythematous, catarrhal, glandulous, scrofulous, syphilitic, lupoid, or cancerous. It may be due to destructive disease of the bones or cartilages of the nasal organs, or of their periosteum or perichondrium; whether the disease be idiopathic, traumatic, or specific. It may be due to the development of adventitious growths in the nasal structures themselves, or in others contiguous to them. It may be due to the deposition of calcareous matters from the secretions, and their aggregation into rhinoliths or nasal calculi. It may be due to the retention of some external foreign body, introduced by design or accident, and to the inflammatory processes resulting therefrom. It may be due to some unfortunate individual or family idiosyncrasy without any ulceration whatever, and even with little inflammation or none at all. It may be due simply to retention of nasal excreta and their decomposition *in situ*.

We have, therefore, to interrogate the part and the system in order to make a satisfactory diagnosis as to the cause of the discharge in any given case, and to form a judgment as to the proper method of treatment.

In order to examine the parts they must be washed out as thoroughly as possible by the use of the nasal douche, and syringes introduced anteriorly and posteriorly into the nasal passages; the best substance in general being tepid water impregnated with table-salt—a drachm to the pint. If this fails to detach the secretions, the phosphates of ammonia and soda or the carbonates of soda and potassa may prove more efficient in like proportion. Sometimes the forceps or the sponge-mop may be used to detach matters within their reach. In order to make a thorough examination of the parts, it is necessary that they be thoroughly cleansed. After the parts have been cleansed they can be examined before a strong light,—anteriorly by drawing the *alæ* aside so as to dilate the passage, or by introducing a speculum; and posteriorly with the rhinoscope. In this way we observe the appearance and condition of the mucous membrane, detect swelling, ulceration, retained secretions, foreign bodies, and morbid growths, exposed cartilage or bone,

etc. The tortuous contour of the turbinated bones and nasal meatuses renders it impossible to examine these structures in their entire extent; but still, under a good light, they can be explored pretty thoroughly, especially with the aid of probes bent so as to admit of application to the surfaces of the various parts, on the same principle employed by the dentist in exploring the tortuous recesses in a carious tooth. Rhinoscopic inspection enables us to examine, in addition, the condition of the glandular tissue at the roof of the pharynx, a structure very frequently implicated in diseases giving rise to the discharge under consideration.

In some cases of fetid catarrh, the bones and cartilages of the nose, as far as their condition can be examined, appear healthy; and no ulceration of the mucous membrane can be detected on inspection anteriorly or posteriorly. There seems to be some constitutional idiosyncrasy in these cases, in consequence of which, retained portions of the nasal secretions undergo desiccation, and remain impacted in some portion of the sinuosities of the nasal passages; there undergoing decomposition. This condition of system has been compared to that which is attended by the peculiar, offensive smell of the cutaneous perspiration from the feet and armpits of certain individuals who cannot rid themselves of their unpleasant odor even by the most scrupulous ablution. In these idiosyncratic cases the discharge is by no means profuse, unless in exceptional instances. Sometimes, indeed, it is quite scanty; but it manifests a disposition to become desiccated into thin scales or crusts, removable only with more or less difficulty: sometimes by way of the nostrils anteriorly, and sometimes by a sort of inspiratory nasal screatus, which, after repeated efforts, forces them through the posterior nasal outlets into the pharynx, whence they are expectorated. These crusts usually emit a horrible stench, perceptible at a distance of several feet, and capable of impregnating a large room with their fetor.

All that can be effectually accomplished in the way of treatment in these cases, seems to be the promotion and maintenance of an active condition of the secretory functions of the skin and kidneys by frequent bathing and copious water-drinking,—keeping up a sort of sewerage, as it were,—and the thorough and efficient cleansing of the parts several times a day, especially at night and morning; making this act a constituent and essential part of the daily toilet, as much so as the use of the tooth-brush or the wash-basin. For this purpose the nasal douche of Thudichum, or some modification of it, is the best contrivance in most instances; but if the crusts are hard to remove, the use of the pharyngeal nasal syringe and of the continuous rubber hand-bellows syringe will afford better results; the latter especially in those cases in which crusts moulded to the contour of the posterior nasal outlet are apt to accumulate, and to dislodge which, readily, a stream of fluid entering with some force from the front is requisite. The ordinary solution of table-salt—a drachm or two to the pint of

tepid water—fulfils the requirements of the douche for cleansing-purposes; and detachment of the crusts is facilitated by the substitution or addition, as may prove most appropriate, of equal quantities of alkalines, such as the carbonate or bicarbonate of soda, phosphate of soda, and the like. At least a quart of the cleansing solution should course through the nasal tract at each night and morning ablution; part of it started through one nostril, and the remainder through the other. After the parts have been cleansed, the douche should again be used, containing a disinfectant in tepid solution. Permanganate of potassa, chlorinated soda, carbolic acid, and so on, employed in this manner, will, in great measure, control the fetid odor of the secretions.

Various local applications are made at times for the purpose of altering the nutrition of the mucous membrane, in the secretion of the glands of which, the diseased action is supposed to reside. For this purpose various preparations of mercury and of iodine, the terebinthines, muriate of ammonia, etc., have been employed in the forms of ointment, powder, solution, and vapor; but, at least in the hands of the writer, they have proved of only questionable benefit.

Local cleansing, with disinfectant detergent douches immediately afterwards, and the maintenance of the cutaneous and urinary secretions by appropriate remedies, have rendered good service; but, to be efficient, resort to these measures must be constant.

Fortunately, in this variety of fetid coryza, the affection, whatever its real nature, moderates in severity as the patient becomes older, so that by middle adult life it has subsided entirely, or in great measure. It is a long while to await permanent relief, to be sure, but it is better than no prospect of cure.

Another form of fetid coryza, attended with certain local manifestations to be described farther on, is engrafted upon the strumous diathesis; and this variety, from its persistence, and from its ultimate destructive results,—which, when very extensive and insufficiently attended to, resemble so much the effects of analogous conditions in constitutional syphilis,—seems to contribute some force to the doctrine that scrofula is but an inheritance of syphilis; modified, it is true, but bearing a relation to that virus similar to that which some authors trace between varicella and variola.

These cases usually originate in an acute coryza or catarrh, the result of exposure to cold. This catarrh gradually becomes chronic, the attendant discharge more or less profuse, varying in color and consistence, being at one time muco-purulent, at another purulent, sometimes sanguinolent, and so on. The odor of the discharge is exceedingly offensive, and there is a permanently unpleasant odor of the patient's breath, rendering propinquity to the individual very disagreeable.

In these cases crusts of inspissated mucus accumulate at the outlets of the posterior nares from detention there of the secretions, and they often become moulded to the form of the opening, pre-

senting, when discharged, a peculiar honeycomb-like configuration. These moulds are usually several days concreting, and become discharged perhaps once or twice a week, sometimes oftener, sometimes less frequently. When discharged at long intervals, small, dense clumps of irregular conformation, and of similar constituents, will be occasionally drawn into the throat by forced nasal inspiration, and be then expectorated. These will possess the characteristic odor. Sometimes small caseous-like concretions will be hawked down, apparently from the glandular tissue at the nasal portion of the roof of the pharynx, similar in appearance to the analogous matters sometimes discharged from the tonsils, and, like them, of an intolerable stench when crushed. In some instances, desiccated crusts can be seen upon the glandular masses at the roof of the pharynx, on pharyngo-rhinoscopic inspection. When examined immediately after spontaneous or artificial removal of the crusts, this glandular tissue is seen to be spongy, and, if the removal has been forcible, is most likely to bear decided evidence of hemorrhage. Pain will be complained of in the parts and will be referred especially to the region of the frontal sinuses.

This form of disease of the nasal passages is met with in all classes of society: in the robust individual no less than in the delicate one; in those who have been tenderly reared, and in those who have been brought up in the roughest manner. It may make its appearance at any age, but seems to be most frequently noticed for the first time about the period of the second dentition. Most of the patients I have seen have been girls from six or eight years of age upwards to confirmed puberty or early adult life.

If, after thorough cleansing with the douche, syringe, or forceps, the parts are carefully examined,—anteriorly by the aid of hook, probe, dilator, or speculum, and posteriorly by the rhinoscopic mirror,—some points of ulceration, superficial or deep-seated, will usually be detected upon the mucous membrane. These ulcerated spots may occupy the free surface of the turbinated bones, or the lower region of the septum; and even when ulceration cannot be discovered in these situations it is often fair to infer that it is likely to exist upon some portions of the turbinated bones altogether out of the field of direct or indirect vision. The nasal mucous membrane will be swollen, often to such a degree as to occlude the passage at one or more points; in some instances the result of sero-fibrinous or fibrinous infiltration into the submucous connective tissue; in others, the result, in addition, of actual hypertrophy of this tissue. In some cases little bags of thickened tissue or exuberant folds project from the walls and are sometimes mistaken for neoplasms. The parts are usually very much congested, though they do not bleed as a rule, except upon rough manipulation; and they are very sensitive to contact with the probe in some instances, and not at all so in others. The mucous membrane of the posterior portion of the septum is often seen by the rhinoscope, pushed off from its sides by submucous infiltration, bulging into the free space of the nasal

outlets so as to present much the appearance of turbid morbid growths.

As a matter of course, in this condition, the patient will experience more or less difficulty of nasal respiration; one nostril or the other, in many instances, being impervious to air, nearly all the time. This induces a habit of keeping the teeth slightly apart to facilitate breathing, and favors the formation of chronic pharyngitis; a condition which is often coincident to all the affections under consideration.

If the disease has existed for a number of years—and it is essentially chronic—the ulcerations will have extended beyond the limits of the tissue proper of the mucous membrane, and will have involved the cartilages and the bones, portions of which will sometimes have been destroyed, and have been discharged spontaneously; so that the cartilaginous septum is in many instances found to have been pierced through, sometimes in one or two small perforations, but more frequently in a single large, irregular hole, perhaps admitting the end of the little finger, or the end of a larger one, and looking as if it had been gouged out with some rude tool. In some instances, one or more of the turbinated bones, usually the middle one, will be necrosed and bare in its entire extent, or the greater portion of it, awaiting its extraction,—an operation readily accomplished with polyp-forceps. Sometimes it has been removed spontaneously, or has been pulled out by the patient, leaving a large, free space in the nostril, through which the posterior wall of the pharynx can be seen, or a portion of the upper surface of the velum. In some instances the destructive inflammation will have progressed to a farther extent, and have involved portions of the superior maxillary bone, from which copious accumulations of fetid pus and necrotic particles will have been discharged at intervals. Cases of this kind will have produced some alteration in the external configuration of the parts, the nose being sunk in or flattened out, and the nostrils distended. In some instances the orifices of one or more sinuses will be recognized, the tracks of which cannot be readily traced, perhaps because they course around the scroll of the turbinated bone. From these openings, on pressure behind them with a probe, a few drops of creamy pus can often be discharged.

Some other evidence of the strumous diathesis is usually apparent.

In cases of undoubted syphilitic origin,—and the distinction between scrofulous and syphilitic coryza is not always well marked,—the involvement of bony structures will progress to a much greater extent than has already been described, the earlier manifestations having been similar to those of catarrhal and scrofulous inflammation, but more active. The turbinated bones, the vomer, the nasal bones, the palate bones, the lachrymal bones, the sphenoid, and the ethmoid, will often undergo more or less destruction. In some instances pharyngeal rhinoscopy and the use of the probe will early reveal necrosis of the vomer, the sphenoid, and the basilar process of the occipital bone. The dis-

charge in these cases is not, as a rule, so offensive in odor as in the scrofulous cases; but it is equally persistent, and will continue as long as any dead bone remains undischarged. The tortuous contour of the nasal passages and the sinuses leading to them is such as to render it impossible in many instances to remove all of this dead bone by surgical interference through the nostrils anteriorly or posteriorly; so that its discharge must be awaited bit by bit. The amount of destruction that the parts may undergo under such circumstances is enormous. In some instances the cranial vault has been pierced, and the resulting meningitis has put an end to the complaint and to the patient.

The amount of the discharge, its consistence, and the intensity of its disagreeable odor, will vary during the course of a fetid coryza, whatever may have been its origin. An inflammation of the parts such as follows a cold, a determination of blood to the head, over-work, the approach of the menstrual flux, all seem to increase the offensiveness of the discharge. This will become moderated after cleansing with the douche, and the application of remedies; but will wax just as bad as ever in a few hours, or a few days. When there is an involvement of bone, or a fresh involvement of bone, the fetor will be increased until the necrosed portion has become exfoliated and discharged.

The patient is usually cognizant of his extremely unpleasant condition to a certain extent, but is unaware of the full amount of stench emitted from his body, because the sense of smell is obtunded, and in some instances entirely destroyed. With the loss of smell there is, in consequence, more or less loss of the sense of taste; so much of it as is dependent on the sense of smell. In those cases in which the frontal and maxillary sinuses are affected to a greater extent than the nasal passages, the patient is better able to appreciate his infirmity, for the sense of smell is still conserved to a considerable degree. The offensiveness of the odor in extreme cases is beyond description, and must be felt to be comprehended. It will impregnate a room for hours, and deter the practitioner from persisting in proper efforts to relieve the local condition.

(To be continued.)

A CASE OF EXTRA-UTERINE PREGNANCY.

BY GEORGE STILES, M.D.,

Conshohocken, Pennsylvania.

I WAS called, on the evening of September 4, 1870, to see Mrs. V., aged 31 years, mother of one child, which was born when she was 21 years of age. She complained of an acute pain, of a pulsating or throbbing character, in the right lower part of abdomen. Her menses, which should have appeared on the 31st of August, had not taken place; and she had been suffering from vague abdominal pains for some three weeks previously. Upon inquiry, I ascertained that she was experiencing morning-sickness, and that her mammae afforded the usual rational signs of commencing pregnancy. From conversation with herself and husband, and

from the evidences of these signs, I concluded that she was about one month gone in pregnancy. I administered the ordinary remedies to relieve her pain and nausea, but with very partial effect; and from that time I was compelled to visit her two or more times daily, in consequence of her very great and continued suffering; to relieve which it was absolutely necessary to employ anodynes in various doses and of various kinds, such as morphia hypodermically, with morphia, opium, hyoscyamus, belladonna, and various other narcotics and anodynes, both by stomach and rectum.

On the morning of the 1st of December I was sent for, and informed that she was threatened with a miscarriage. On examination, I found the mouth of the uterus closed, but that blood was escaping freely from its cavity; her pulse was 126; the abdomen tympanitic; extremities cold; her face ghastly pale; no nausea. Concluding that all hope of saving the ovum was gone, I gave a full dose of fluid extract of ergot, and in a few hours the hemorrhage entirely ceased. In a few hours later, however, she was seized with intense pain in the abdomen, uncontrollable vomiting, and all the symptoms of acute and violent peritonitis. Pulse 120; her abdomen enormously swollen, and sensitive to touch; constant vomiting; bowels obstinately constipated; the bladder had to be emptied by the use of the catheter. So grave were the symptoms that I thought she would die. The main treatment consisted in giving enormous doses of opium by the rectum, and the application of ice to the abdomen. At the end of three days she was decidedly better; pulse diminished in frequency; stomach retained small quantities of suitable food; bladder acted spontaneously, and the bowels were finally moved (after repeated failures by other purgatives) by a dose of oleum tiglii. Five days later, all the symptoms returning with all their original severity, Dr. Hiram Corson was called in consultation, who, after a careful examination finding the uterus in its normal position, but somewhat enlarged, and detecting no other local signs of pregnancy, expressed it as his belief, from the history of the case, that she was pregnant, but that her sufferings came more from a highly hysterical condition than from anything else; and suggested the disuse of anodynes, and the substitution of quinia, three times daily, with ice applied externally to the abdomen. This treatment was continued for two or three days, when the pain in her abdomen became so excessive that it was absolutely necessary to return to larger doses of anodynes than ever, with the aid of which it was with great difficulty that sleep could be produced, or any relief could be obtained.

For the next three weeks her symptoms were of the gravest and most urgent character. Abdominal pain intense, only relieved imperfectly by enormous doses of anodynes; her nausea so unremitting that life could only be sustained by milk and beef-essence, administered by rectum; her pulse feeble, and always over 100; belly tympanitic and excessively tender; the bowels constipated.

In the month of January, 1871, I made the following notes of the case:

January 6.—Mrs. V. spent a terrible night, but this morning is somewhat easier; has slept nearly all day.

January 8.—Passed a better night. Bowels spontaneously moved this morning; pulse 110; skin moist and quite cool; complains of nausea after taking food.

January 12.—Much better this morning than for a long while. Bowels moved daily since the 8th inst.; takes food kindly; pulse 100.

January 26.—Up to this time Mrs. V. has been steadily improving; to-day sat up in her room for four consecutive hours; eats heartily; daily evacuations from bowels; sleeps well at night; pulse 90.

January 29.—Mrs. V. came down-stairs yesterday for the first time; thinks she is able to look after her household duties; a good appetite; functions apparently all normal. From this time I discontinued my visits.

On the 6th of February she visited an uncle in Philadelphia, and appeared in good health.

On the 7th I was called to see her. She had reached her home in great suffering, and from this time her symptoms became very grave; the abdomen was as much enlarged as is usual at the end of the eighth month of gestation, and exceedingly sensitive to the touch. Her pulse remained at about 120; her nausea was constant, and all food was almost instantly vomited; her abdominal pain was so severe that the largest doses of anodynes gave but little relief,—the usual quantity being as much as nine grains of opium in twenty-four hours, or one and a half grains of morphia.

As she was becoming exceedingly emaciated, I began to entertain grave doubts of a normal pregnancy; and on the 26th of March, 1871, I called in consultation Professor Penrose, of the University of Pennsylvania. She then presented the following appearance and condition: Face pale and haggard; mind somewhat disposed to wander; pulse 120, and feeble; hands cold; abdomen very much distended, and so sensitive that it was a matter of discussion whether she should not be etherized, so that a more thorough exploration could be made. Palpating the abdomen, a tumor was easily recognized, about the size of the uterus at the beginning of the eighth month of pregnancy, and in the median line, while above and on either side of the tumor the sound of percussion was very tympanitic. This tumor was firmer and harder than the pregnant uterus, and appeared of uniform consistence.

A vaginal examination revealed the mouth of the uterus carried close against the symphysis pubis; the cervix somewhat softened, and admitting the index-finger an inch. From the posterior lip of the uterus, and directly continuous with it, could be traced a firm, hard tumor, which filled the whole of the upper part of the pelvic cavity, and seemed to be part of the abdominal tumor dipping into the pelvis. This mass was as firm and hard as a fibroid growth, and *ballotement* could detect no movable body in or above it. A most careful exploration of the abdomen revealed no sound of foetal heart or of foetal movements.

Dr. Penrose considered the case a very obscure one. That the enlargement was not caused by a natural pregnancy he considered almost certain, in

consequence of the density of the tumor, the absence of the foetal heart-sounds, as well as of the signs furnished by the active and passive movements of the child; and, besides all these, the very singular position of the os uteri, close to the symphysis pubis, is never met with in normal gestation. But then, on the other hand, there had been menstrual suppression for seven months, while in the beginning of the case there had been morning-sickness and the early mammary alteration characteristic of pregnancy; and now here was an abdominal tumor in the position and of the size usual at or about the end of seven months.

Dr. Penrose suggested the probability of an extra-uterine pregnancy, and referred to a case the history of which had been recently sent him from North Carolina, in which some of the conditions, especially the very singular one of the position of the os uteri, resembled those furnished in the present instance; but in this case the foetal heart-sounds and foetal movements could be distinctly recognized, while here there were no heart-sounds, no foetal movements.

Dr. Penrose thought that there might be some growth—possibly malignant—which had caused the rapid enlargement and terrible suffering. He had no hesitation, however, in giving his opinion that, as the case was so obscure, it was barely possible that pregnancy might exist, and hence no active interference ought to be attempted until after the full period of gestation, and the only treatment to be pursued was that which she had been receiving—viz., rest, anodynes, nourishment. When the patient's husband requested the Professor's prognosis, he said that he considered the woman so ill that he believed she would die before the full period of gestation was reached, and requested, should death take place as he expected, that a post-mortem examination should be made. Ten days later some relatives of the family requested that Dr. Washington Atlee, of Philadelphia, should be called to see her. After a hurried examination, Dr. Atlee expressed it as his opinion that she was either pregnant or suffering from ovarian tumor; that the pain in the abdomen was hysterical; that she was not so seriously ill as Professor Penrose stated, but that she would certainly live for some months, and probably get well. He differed from Professor Penrose as to treatment, recommending exercise, abstinence from anodynes, and that her mind should be educated to look upon her sufferings as the result of a hysterical fancy. From this time until her death, which occurred three days after Dr. Atlee's visit, her symptoms increased in severity; she became constantly delirious, with vomiting, and uncontrollable pain. Forty-eight hours before death, suddenly, copious evacuations of altered blood with traces of pus were passed from the rectum, amounting in quantity by measure to one-half a gallon; and from this time she rapidly sank, dying on the morning of the 7th of April, 1871. On the evening of the 8th of April, a post-mortem examination was made by Professor Penrose and myself. On cutting through the abdominal walls it was found that the whole peritoneal cavity had been

entirely obliterated by universal peritonitis, which peritonitis had evidently lasted for a long time,—doubtless since the attack in December previous. So firm were these peritoneal adhesions that the knife could be used only with great care, and the contents of the abdominal cavity had to be separated from the walls by tearing with the fingers. After some time the whole mass of abdominal contents was removed, and not until then was the nature of the enlargement recognized. The case had been one of extra-uterine pregnancy; the cyst had ruptured and had discharged its contents into the peritoneal cavity months previous to death,—doubtless at the time of the sudden hemorrhage and acute peritonitis in December. The dead foetus, about four months old, thoroughly softened and macerated, was found surrounded by coagulated blood with some pus, and the whole encysted in a cavity, the walls of which were formed by the hardened and thickened adjacent surfaces. The relative positions of the various component parts of this mysterious abdominal growth were as follows. In front was the uterus, enlarged, as will be seen by the description, its cavity empty. Behind the uterus, and forming the hard fibrous projection into the pelvic cavity which had seemed to the touch, before death, to be part of the posterior uterine wall and to be continuous with the posterior lip of the uterus, was an oval mass of solidified blood, appearing, after removal from its position, as large as, and somewhat the shape of, an ostrich egg. Above this hard oval mass of solidified blood was the body of the foetus, its head directed towards the posterior part of the right iliac fossa, the breech to the left iliac fossa, while above and around the foetus were coagulated blood and pus.

This mass of abnormal structures was carefully removed, and sent by Professor Penrose to Dr. W. F. Jenks, an eminent accoucheur of Philadelphia, for a microscopical examination, with the following result:

The bladder was contracted. An incision which was made with the intention of dividing the anterior wall of the uterus, opened a cavity about the size of an orange, the anterior wall of which was formed by the abdominal walls and the fundus of the bladder, while the enlarged uterus and right broad ligament formed the posterior boundary. This sac communicated by ragged ulcerated openings with a cavity which subsequently proved to be the distended right Fallopian tube. The lower portion of the peritoneum, which formed the lining membrane, was discolored by old hemorrhagic effusions. The contents had mostly escaped; there remained, however, a small amount of a dark, opaque, brownish fluid.

The uterus was six inches in length, three inches in breadth, its walls three-fourths of an inch in thickness. The mucous membrane was thickened and injected. It was impossible to trace the left Fallopian tube. The lumen of the right tube was occluded a short distance from the internal orifice. By forcing the sound through this obstruction it passed into a sac with irregular jagged edges, below which the right round ligament was traced, and beyond it to the right the ovary was recognized, showing that the walls of this cavity, which were about one-eighth of an inch in thickness, were formed by the distended Fallopian tube. The left ovary was small, but normal. The right ovary was

reduced to a thin, flattened plane of fibrous tissue, containing a number of Graafian follicles which had undergone cystic degeneration.

These structures—viz., the posterior wall of the uterus, the right and left broad ligaments, and the remains of the ruptured sac, formed by the left Fallopian tube—constituted the anterior wall of a large cavity, which was bounded in all other directions by the small intestines and rectum, which were glued together by peritoneal inflammation. The walls of this sac were one-fourth of an inch in thickness, and consisted of layers of lymph, discolored by old hemorrhages. Its contents had been removed at the post-mortem examination.

Diagnosis.—Right tubal pregnancy; rupture of the sac at the third month; general peritonitis, resulting in the formation of a secondary sac around the foetus.

THE RESONANT FUNCTIONS OF THE EXTERNAL EAR.

BY CHARLES H. BURNETT, M.D.,

Aural Surgeon to the Presbyterian Hospital in Philadelphia, and to the Philadelphia Infirmary for Diseases of the Ear.

IN a recent number of this journal (October 4, 1873) I alluded to certain phenomena of resonance which I had observed in connection with the external ear, but I did not venture beyond the simple description of these phenomena and a localization of them in various parts of the external ear. It is my intention in this article to give an explanation of the physical causes of the *resonant functions* of the external ear, referred to at that time (*loc. cit.*); and under the term external ear I shall include the meatus auditorius externus, and auricle, or pinna.

The auricle, in combination with the meatus auditorius, forms a resonator of a more or less conical shape, closed at the bottom by the membrana tympani, the special function of which is to strengthen by resonance those waves of sound which possess a short wave-length.

Let the accompanying diagram represent a section of the external ear, from the membrana tym-

DIAGRAM REPRESENTING THE TOPOGRAPHICAL RELATION OF THE COMPONENT RESONANT CAVITIES OF THE EXTERNAL EAR.

a., fossa of helix; *b.*, fossa of antihelix; *c.*, concha; *m.*, meatus auditorius externus; *t.*, membrana tympani.

pani to the helix. The section is made from above downwards, parallel to the long axis of the meatus auditorius externus, and gives an ideal representation of the manner in which the resonator we shall consider is built up by the auditory canal and the successive columns or cups of air, represented by the concha and fossæ of helix and antihelix.

The widest diameter of this resonant cone or funnel, or miniature "speaking-trumpet," *i.e.*, the diameter obtained when the helix and lobe are made to approach each other about the opening of the external meatus as a common centre, does not exceed the wave-length of the note to which the resonator thus formed will respond. In order fully to understand how this resonant power is maintained by the external ear, and to sound-waves of what length it specially resounds, let us first consider the resonance of the meatus auditorius externus, and the physical reasons for such a function in it.

We know that the external auditory meatus resounds to the notes e^{iv} to g^{iv} (Helmholtz's *Tonempfindungen*, p. 175, 1870), and we also know that the column of air which most easily resounds to any given note is equal to one-fourth of the length of the wave of sound produced by that note (Tyndall "On Sound," p. 174, 1869). Now, the wave-length is found by dividing the velocity of sound per second by the number of vibrations executed by the sounding body per second (Tyndall, *op. cit.*, p. 84), and the quarter of the result of this division, *i.e.*, the quarter of the wave-length, will equal the length of the column of air which will act the part of a resonator for the note producing the sound-wave.

In order to appreciate this fact, let us work out a simple problem in physics, with the data before us, as follows. As already stated, the notes e^{iv} to g^{iv} have 2640 to 3168 vibrations per second, and the velocity of sound in atmosphere at 15° C. is equal to 1122 feet per second. Therefore, the length of the wave produced by the note of 3168 vibrations per second will be found by dividing 1122 by 3168. The answer will be, about three-eighths of a foot, or four and a half inches.

Now, the column of air which will resound to the note producing a wave of that length is equal to one-fourth of that wave-length, or one and one-eighth inches, which is just the short average length of the meatus auditorius externus. Some authorities give one and one-fourth inches as the average length of the meatus auditorius externus, but practically the normal human meatus has various lengths, passing gradually from the meatus proper into the concha; and this brings us to the second consideration connected with the phenomena of resonance manifested by the external ear, viz., that as the pitch of a note, let us say of e^{iv} or g^{iv} , falls, the wave-length must become greater, or, in other words, as the number of vibrations per second diminishes, the wave-length increases; which is but the enunciation of a common law of physics. It is now manifest that the column of air contained by the meatus auditorius externus will not be long enough to act as a resonator for waves of sound the quarter of which is represented by one and three-fourths to two inches.

Therefore, we find the concha superposed by nature upon the external auditory meatus, in order to lengthen it. We have already seen by experiments last summer that the notes which resound to the column of air represented by the concha, *i.e.*, the concha in conjunction with the meatus auditorius

externus, are lower than those which resound to the external auditory meatus when it is made to act alone, which we can accomplish by pushing the concha out of place by firm pressure of it against the head. The reason for this becomes very clear when we reflect that a note lower than those represented in the scale from e^{iv} to g^{iv} must have a greater wave-length, and therefore it requires a longer column of air as a resonator. If this lower note should fall in the octave below those notes already mentioned, the addition of the column of air in the concha to that of the meatus would supply the resonator.

If to this resonator, composed of meatus and concha, we add the fossæ of the antihelix and helix, we of course obtain longer or deeper resonating columns of air; and I know from my experiments that notes of still greater wave-lengths than those alluded to resound to the column of air represented by that contained in the fossæ of the auricle added to that of the concha and meatus auditorius externus.

By holding the hand behind or around the ear, we have the power of adding a still deeper column of air and its resonance to that of the external ear. Hence, the deaf person involuntarily places his hand to his ear, to increase, by resonance, the ordinary sound falling upon it. His hearing is thus strengthened, especially for those notes of high pitch and short wave-length to which the human voice owes its peculiar timbre or clang-tint. "It is indeed remarkable that the human voice should be so rich in over-tones (Obertöne), for which the human ear is so sensitive." (Helmholtz's *Tonempfindungen*, p. 176, 1870.) When the wave-length increases, as it does when the note becomes still lower than any of those alluded to, the resonance of the external ear ceases to exert any marked influence on the fundamental note. In such a case it is probable that the resonance of the room or street in which we are placed is aroused by the longer wave of sound; but nature has supplied us, in the external ear, with an ever-present and delicate resonator for just those notes of short wave-length in which the human voice is so rich and to which it owes its special timbre.

I would like to state here that these phenomena of resonance peculiar to the external ear were communicated by me to my friend Dr. A. H. Buck, of New York City, shortly after I had observed them last summer, and that, during the hours of travel which we spent together, the experiments were performed by him upon his own ear, with a verification of them satisfactory alike to him and to me.

We may, therefore, conclude that the external ear (*i.e.*, the meatus auditorius externus and the auricle) forms a resonator for those tones having wave-lengths the quarters of which are represented by the various depths of the column of air contained by the external ear.

The various interesting questions concerning the resonance of isolated portions of the auricle—*i.e.*, of the fossæ—when acting alone as resonators, as well as the comparative resonance of the meatus auditorius externus, shall, as I hope, form the subject of

a future paper; but I would like to state now that the absence of a developed auricle in birds or insects is not, in my opinion, an argument against its utility as a resonator in man, for the wave-lengths of the high notes which these inferior animals must both use and hear as a means of intercourse with each other, are so short that they will resound perfectly well in the shallow auditory meatus found in them.

* TRANSLATIONS.

CHRONIC PSEUDO-MEMBRANOUS PERITONITIS.—Dr. Ch. Bäumler, of Erlangen (*Virchow's Archiv*), reports the post-mortem conditions found by him at the autopsy of a patient who died of Bright's disease in the German Hospital in London, upon whom the operation of paracentesis abdominalis had been repeatedly performed. The patient was a man aged 30 years, who, eight years before his death, had suffered from intermittent, which was followed by a general swelling over the body. Five weeks previous to his admission into the hospital on June 14, 1864, he had persistent epistaxis, and two weeks later, swelling of both feet came on. At the time of his admission he had general anasarca, and marked œdema of the legs. With the exception of a slight cough, there was nothing abnormal in the condition of the thoracic viscera. The area of splenic dulness was enlarged, that of the liver was normal. The urine at this time varied from 1200 to 2000 cubic centimetres in amount, was markedly albuminous, and contained tube-casts. From the time of this first admission until June 27, 1865, when he was admitted into Guy's Hospital, he suffered but little from œdema, but the urine still contained albumen. At this time the dropsy had become so marked that tapping was resolved upon, and was performed on the 4th of July, when 13,700 cubic centimetres of clear, yellow serum, containing albumen, were drawn off.

The operation was repeated on the 14th of the same month, and at this time much blood was mingled with the fluid drawn off, and the operation was followed by symptoms of peritoneal inflammation. Tapping was performed on several subsequent occasions, but the patient finally died of œdema of the lungs on the 15th of November, 1865. At the autopsy the legs were found œdematous, and upon opening the thorax there was found in the right pleural cavity some fluid containing blood, and there were also some threads of fibrin extending from the lung to the walls of the chest. The left lung was œdematous throughout. The heart and aorta were normal, with the exception of a slight thickening of the valves. Upon opening the abdomen a closed sac was found containing a loose mass of fibrin, in the interstices of which was a greenish-yellow fluid. The walls of this sac were three millimetres in thickness; their outer layer was fibrous, the inner somewhat less dense in consistence. None of the abdominal viscera could be seen until the posterior wall of this sac had been removed, back of which they lay. The thickness of the posterior wall was found to be about the same as that of the anterior wall, and the intestines were only loosely attached to it by organized adhesions. There was no connection with the liver, so that that organ bore to the posterior wall of the sac the same relation that it usually has to the parietal peritoneum. The surface of the false membrane towards the intestine, as well as the peritoneal surface, was deeply pigmented and smooth, like a serous membrane. The false membrane could be readily separated from the intestines, and also into several distinct layers. The perito-

neum beneath the false membrane, which probably was formed from the effusion occurring after the second puncture on the 14th of July, was in some places much thickened. A microscopic examination demonstrated that the false membrane was composed of fibrin with some fatty nuclei. The left kidney was found to be thoroughly disorganized, and adherent to the sac; the right was large and fatty. The spleen, left supra-renal body, pancreas, and the remains of the left kidney were all adherent to each other. From the apex of the bladder the false membrane extended to the promontory of the sacrum, completely separating the true pelvis from the cavity above.

The pigment found in the visceral peritoneum and the adjacent surface of the sac is an evidence that at one time there was great vascularity of the parts, and that there was hemorrhage after the first tapping; and it is possible that the parts were vascular up to the time of death, and that the blood only left them at that time.

ACTION OF CHLORAL ON ALBUMINOID MATTER.—At a *séance* of the Académie de Médecine, held February 10, 1874, M. Personne presented the following summary of his experiments on this subject:

1. Fresh blood, to which hydrate of chloral has been added at an ordinary temperature, coagulates completely, preserves its red color, and remains without alteration at a temperature of 77° to 82° Fahr. When coagulated, it is insoluble in water.

2. Defibrinated blood, treated in the same manner, coagulates, but the coagulum is partly soluble in water. The dissolved matter has not been studied.

3. A morsel of muscle immersed in a ten per cent. solution of chloral becomes pale "flesh-color," and exudes a small quantity of reddish liquid, which deposits a brick-dust sediment. After exposure to the chloral solution for some hours the muscle loses the power of putrefaction, and exposed to a temperature of 60° to 78° Fahr. dries rapidly, and becomes friable. Dried at 212° Fahr., it constitutes a combination of chloral with the albuminoid matters of the tissues.

It does not furnish chloroform when treated by alkalis.

Like the combination of albumen with bichloride of mercury, it possesses the property of being soluble in an excess of either of its constituents, making its production a matter of some difficulty.

4. These facts suggested to M. Personne the idea of using chloral as a preservative for anatomical preparations, and he presented to the Academy a guinea-pig and a dog, the first of which had been injected with chloral solution four months previously, and the other eight weeks. Both were perfectly preserved.

Portions of muscle preserved in the chloral solution alone became dry and pulverulent, but if this was mixed with an equal quantity of glycerin they remained quite soft. A cerebellum was shown which had been preserved several months, and was still soft, fresh, and in excellent condition for anatomical investigation.

A. V. H.

EXPERIMENTS ON MECHANICAL ICTERUS.—M. Audigné presented, at a recent *séance* of the Société de Biologie, the liver and its appendages from a dog in whom the ductus communis had been ligated. The animal survived the operation nineteen days, emaciating rapidly, although having a voracious appetite. Within four hours subsequent to the operation, the urine, which had previously contained no trace of biliary coloring-matters, gave evidence of their presence in large quantity, and within a day or two the fæces were completely decolorized. The icteric tint of the

skin did not show itself until the eighth day, from which period it became rapidly more marked, and finally could be observed in the mucous membrane of the mouth and nose. The animal finally succumbed with symptoms resembling those of uræmic poisoning.

The autopsy showed the liver to be enlarged and congested, with dilatation of all the biliary passages. Under the microscope the capillaries and vessels generally were found dilated. The lymphatics were filled with a citron-colored fluid, which was also observed in the thoracic duct.

That previous observers have not found bile appearing in the urine so soon after ligation of the common duct, is due, M. Audigné thinks, to the ligation not having been performed sufficiently close to the intestinal outlet; some of the afferent branches of the common duct joining it very near the intestinal wall. A. V. H.

ARSENIC IN THE FURUNCULAR DIATHESIS.—M. De Savignac (*L'Abeille Médicale*) makes use of arsenic in the treatment of the furuncular diathesis in the following way. Internally he prescribes,

R Sodii arseniat., gr. ii;
Aqua, f̄ssv. M.

Of this mixture a teaspoonful in a little sweetened water is taken twice a day for three weeks. At the end of that time the arsenic is suspended, and for ten days sulphate of sodium is administered daily, in doses of half an ounce to an ounce.

He returns then to the arsenic as before, repeating the course of treatment, if necessary, three or four times. Occasional doses of decoction of dandelion or sarsaparilla are also administered, and the patient is confined to a diet chiefly vegetable.

Externally, poultices and, later, diachylon are used; and if the tubercles occur in groups, and are quite hard, the following emollient application is employed:

R Sulphuris sublimat., ʒss;
Pulvis camphoræ, ʒii;
Unguent. aq. rosæ, ʒiiss. M.

A. V. H.

LOCAL APPLICATIONS IN NEURALGIA.—*Chloroform.*—Dr. Dupuy speaks very highly of this remedy used as follows. A pledget of lint moistened with chloroform is to be applied to the painful locality, and retained in position a longer or shorter time, depending upon the age, sensitiveness, etc., of the patient, and the part operated upon. Usually, half a minute to five minutes is sufficient, and the application may be renewed from one to a dozen times. Dr. D. states that recent and superficial neuralgias yield to one or two applications, and that even in severe sciatica of long standing he has never been obliged to make more than twelve.

Blisters to apophysal points.—The constant presence of such points in neuralgias, as shown by M. Armain-gault, has led to the use of blisters applied in their immediate neighborhood, with very satisfactory results. In cases of facial, intercostal, lumbo-abdominal, and sciatic neuralgias, even when of the most persistent character and rebellious to other forms of treatment, this plan has been found effectual.—*L'Union Médicale*, Nos. 19 and 20, Feb. 1874. A. V. H.

PRESENCE OF LEAD IN THE BRAIN.—M. Troisier (*Le Mouvement Médical*), while making a chemical analysis of the brain of a patient who had been a worker in lead for more than thirty years but had never presented any signs of brain-disease, discovered well-marked traces of the metal.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 4, 1874.

EDITORIAL.

THE ANNUAL OVERFLOW.

WE have already stated our opinion that the faculties of our colleges are not to be blamed for the disgracefully low standard of graduation which prevails, and that they are not to be expected to alter it: it only remains to give the reasons for this opinion. In the first place, let us look at the matter from the stand-point of one of the incumbents.

An ambitious young man determines, if possible, to become a professor in a leading medical school, and arranges his plans and mode of life in accordance with this desire. The amount of unpaid work which he does is simply enormous, and, lured by the mere chance of success, he sacrifices ease, and what to other men are the pleasures of life. All this toil and all this sacrifice, it must be remembered, go for nothing if the aspirant does not finally attain his goal. So far from bringing an immediate reward,—unless it be the chair of surgery, of obstetrics, or of practice, which is coveted,—these labors undoubtedly lessen the chance of rapid success in practice; for practice, like a coy maiden, must be wooed with a single eye, and the dear public will pet a man who spends his nights in the ball-room, club-house, or theatre, but will contemptuously call the physician who uses the same time in the laboratory a chemist, vivisectioner, bug-hunter, or what not. In this round of unremunerative labor the years pass, until in middle life, after a hard canvass, in which others, who have striven

perhaps as hard as himself, suffer shipwreck, our hero is installed in the place of his ambition, and is overwhelmed by the congratulations of his friends. Full of zeal in the first flush of success, he looks around to see how he can carry out the long-cherished desires for reform. He finds that, his practice being only one-half that of his former class-mate, when his professorial fees are added the whole sum foots up two-thirds of the income of his less ambitious and perhaps less gifted neighbor, who has not pursued baubles, but the solid rewards of practice. He finds that he is a member of a highly respectable faculty and of an organization as rigidly crystallized as the quartz of his native hills. He finds, also, that if he conforms with this organization, at the end of the year he has some twenty-five hundred or three thousand dollars in his pocket; not an excessive honorarium for the work done. If he attempts to alter the organization, he soon perceives that it is hard to kick against the pricks, and that the probabilities are much greater in favor of his being crushed by the car of Juggernaut than of his stopping it. He inevitably—moved by self-interest and chained by stern necessity—slides into the traces, and pulls, side by side, shoulder to shoulder, with the first men in the medical profession of the United States. He were, indeed, a man of strange fibre that, under the circumstances, would offer himself for immolation.

These things being so, it is evidently folly to expect reform to come from within the faculties. A board of trustees, having the power and having themselves no pecuniary interest in the matter, may force the faculty into the change. But, unless they attach salaries to the chairs, such proceeding, although for the general good, would be arbitrary and unjust to the professors. Especially, however, is it unjust in the profession to expect the faculties to originate reforms. In the proposed changes the professors have nothing to gain and everything to lose, whilst the profession has everything to gain and nothing to lose. What right, then, has the profession to expect the faculties to inaugurate the reforms? With what justice does the profession ask the professors to sacrifice their livelihoods for a reform which can redound only to its (the profession's) good, and for which the profession will not make the slightest effort? The sacrifice must be made by some: let it be by those who gain by it. Let it be by those whose numbers will so divide it that each individual will scarcely feel his share.

There are two ways in which it is conceivable the profession could effect the desired change. That which is least practicable, because requiring greatest

consentaneousness and persistency of action, would be for the profession to force, so far as lies in its power, medical pupils to go to those colleges which adopt the advanced system. Thus, if our city schools found that a third, or even a fourth, of their classes, owing to the efforts of their own alumni, were going to Harvard, it would not be long before their courses would be prolonged. In other words, let the profession make it the interest of the schools to raise their standard, and they will do it.

Another, and seemingly far more practicable, as it is more just, method of reform, is for the alumni to raise endowment funds. It is certainly directly to the interest of practitioners that the present manufacture of rivals by steam should be checked. There must be nearly four thousand living alumni to either of the large medical schools in this city, and an average of fifty dollars each would yield a sum of \$200,000 for each school, a sufficient endowment to start with. In order to secure the end, however, it would only be necessary to get a fourth of that sum paid in, and then let this be put out at interest, and in course of time the endowment would be in hand. Some of the alumni are rich, and assuredly it would not be difficult to obtain a number of subscriptions ranging from five thousand to five hundred dollars. Moreover, we think that no trouble would be experienced in obtaining subscriptions from gentlemen of wealth to aid the effort, if the profession showed itself in earnest by subscribing liberally itself; and the complete success of any such movement, if properly managed, seems to us assured. Certainly, if it were to fail, we ought all to hang our heads, and forever hold our tongues "about our high and noble profession,"—talk which, in view of the doings of commencement-day, has always seemed to us at best balderdash. In the name of a profession which ought to be high and noble, we hope some one will make the effort, and that clamor against or about the faculties will cease in action. Let those who have talked loudest do most.

In some of the New York colleges the effort is being made to raise endowment funds for new chairs. We are not entirely *au courant* with the movement, and may misconceive it; but, as we understand it, we do not like its drift. It is not new professors, on whom students may or may not attend, but forcing the students to know that which is at present taught, that is needed. When the present professors are independent of their scholars, it will be time enough to raise endowments for new chairs.

THE COMPLIMENTS OF THE SEASON.

THE *Medical and Surgical Reporter* renews, in a late issue, its attack upon this journal, or, rather (for the attacking party is evidently trying to haul off), feebly replies to our notice of its original assault. It reiterates its incorrect statements, and calls us a phoenix, without in any way meeting the very distinct points we made in our last editorial,—a procedure which reminds us of the boy who, getting the worst of a fight, begins to blubber, "I'll tell my mother on you." We may be a phoenix; if so, we must be a young, vigorous one, and have nearly five centuries of life before us,—not a very unpleasant prospect; but if ever by reason of age we get as feeble as our venerable cotemporary, we trust our friends will see that we mount the funeral pyre before the appointed time. We are further likened to "Vholes;" our obliquity of vision is commented upon, and in a characteristic clause, in which the words (omitting the prepositions and articles) average ten letters each, we are read a lesson upon the "proprieties," all simply because we advertise. We remember once to have been in a boarding-school in which there was read every week a fierce blast against the use of tobacco by a governor who, when he came to the passage, rolled the delicious quid into the farthest corner of his mouth. We are afraid our friend, in writing concerning the proprieties for our reproof and edification, must have seriously endangered himself; for, being in possession of the knowledge that the *Reporter* advertises as much as it knows how, and remembering also how with one hand he had filched our columns for editorial and with the other had smitten us hip and thigh, he must surely have actually swallowed the quid.

THE Philadelphia correspondent of the *Boston Medical Journal* says in a recent letter:

"It is said that the remains of the twins will now be carried through the States on exhibition; that the loving widows are filled with a burning desire to make the twins profitable even after death; that, however, strenuous opposition to this delightful and savory plan has arisen on the part of an invalid daughter of one of the brothers. There may yet be an opportunity in Boston to gaze upon the forbidding, shrivelled remnants of Chang and Eng."

The correspondent is scarcely to blame in echoing the universal report in regard to the family of the twins, but we trust that in his next letter he will correct what is in truth an atrocious libel. It seems that the widows of the twins were

persuaded, by the conjoined eloquence of their usual legal and medical advisers and of the commission, to allow the bodies to be brought North. The two sons of the deceased were living in the far West, and, on arriving at their homes, were overwhelmed with mortification and grief at learning the course events had taken. Week before last they arrived in this city, and a sadder couple it has rarely fallen to our lot to see. When Prof. Allen, as they stood with tears in their eyes before the corpses, expatiated upon the perfectness and success of the embalming process, they heard him through quietly. As soon as he had finished, very sadly and very earnestly one of them asked, "Doctor, is it possible to undo this? Can the fluids be taken out? We would give anything to have the bodies as they were." Their grief was evidently very real, and we would not have dragged it even thus far into publicity had it not been for their evident desire that the public should know their abhorrence of all that has been done in the matter. If the young men, who are now the heads of the respective families, had been at home at the time of their fathers' death, the bodies of the twins would never have reached Philadelphia.

THE past season has been a very successful one with our medical schools,—the Jefferson graduating 151 men, and the University 121. Considering the great disadvantages the latter institution labored under in being, as it were, houseless, and dwelling in the tents of a strange people, we think both the faculties are to be congratulated on their success. We do not doubt that the standard of graduation with these schools is as high as that of any similar institution in the country, always excepting noble Harvard, and the opportunities they offer for clinical study are almost unrivalled.

If any student has the nerve and muscle to contend with New England climate, customs, and examination, and desires to get the most valuable diploma in the country, Harvard should be the school of his choice, and Boston his wintering city. To those of not such robust faith, purpose, and ability, we can heartily commend Philadelphia and its colleges.

WE are indebted to Dr. J. L. Bodine, of Trenton, for the knowledge that the bottle of medicine and the stomach of the deceased James A. Grant, the victim of the alleged poisoning some time ago commented on in our columns, have been sent to Prof. Rogers for examination.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, FEBRUARY 26, 1874.

VICE-PRESIDENT, DR. H. LENOX HODGE, in the chair.

DR. MORRIS LONGSTRETH presented a specimen of intestine containing *multiple intussusceptions*. The patient from whom it was taken suffered an injury of the fore-arm, for which amputation was performed. For some time previous to death, which occurred from obscure causes, he had had a profuse diarrhoea. At the autopsy there were found eight invaginations of the small intestine, all occurring in its upper-half portion. The largest was not of a greater extent than three inches, while the smallest was not over half an inch. They were easily reducible, three of them having been pulled out previous to the specimen being brought before the Society. There were no evidences of any inflammatory trouble at these points or at other portions of the abdominal cavity. No lymph or adhesions, nor any congestions, were found in any portion of the intestine.

Dr. H. LENOX HODGE asked whether there were no symptoms previous to death pointing to the condition of the bowel.

Dr. LONGSTRETH replied that there were none except the diarrhoea alluded to in the history of the case.

Dr. WHARTON SINKLER recalled a patient who died of phthisis, and in whom a number of intussusceptions were found post mortem, but he was also the subject of diarrhoea before death.

Dr. JAMES TYSON had met, occasionally, in adults as well as children, intussusceptions which had not been suspected before death; the important difference between these and those which gave rise to symptoms before death being in the presence of peritonitis, of which they became a cause. He referred to the specimen which he had presented at the previous meeting, and which was taken from an infant in whom there had been diffuse peritonitis with obstruction before death.

Dr. A. C. W. BEECHER presented a specimen of *intussusception* taken from a child less than fifteen months old, in which there were five intussusceptions (four existing at present, one having been pulled out) in a portion of small intestine two feet in length. They are all invaginated in the same direction, two of them extending fully an inch and one-half. There are no inflammatory deposits or adhesions. There were no symptoms before death pointing to this condition, and he was not looking for it when it was found. He had also found at about the same time, while resident physician at the Philadelphia Hospital, similar unlooked-for intussusceptions in very young children whom he had examined post mortem, but not so many invaginations in so short a piece of intestine as this.

Dr. H. LENOX HODGE exhibited *sections of the condyles of the femur and of the head of the tibia and the patella*, removed to-day by exsection of the knee-joint, at the Presbyterian Hospital. The patient is sixteen years of age, and is in good condition. He has suffered from arthritis of the right knee for about five years. A year ago he was in a hospital for three months, under treatment by rest and counter-irritants, without permanent benefit. Since then he had suffered much pain, and been obliged to use crutches when he moved about.

The semilunar cartilages have been completely destroyed, and in several places the articular cartilages on both the femur and tibia, and at these positions the bone is carious. Upon making the sections with the

saw, the bone above the joint was found softened. The patella and its cartilage are less diseased than the femur and tibia.

Dr. HODGE asked the opinion of the members as to the probable cause of the complete destruction of the semilunar cartilages.

Dr. JOHN ASHHURST, Jr., said that, according to his experience in those cases in which the disease originates in the synovial membrane, particularly in cases of gelatinous arthritis, the semilunar cartilages disappear at a comparatively early period; whereas in those cases in which the disease originates in the extremities of the femur and tibia the articular cartilages suffer more, and the semilunar cartilages are found comparatively unaltered.

Dr. HODGE asked Dr. Ashhurst whether he had ever met cases in which there was not a trace of the semilunar cartilages left.

Dr. ASHHURST replied in the affirmative.

Dr. JAMES TYSON presented a specimen of *enormous hypertrophy of the heart* which had attended marked contraction of the kidneys in a patient dying at the Philadelphia Hospital. There was no valvular disease except slight thickening of the mitral valves.

The kidneys exhibited in a striking degree, to microscopic examination, the hypertrophied condition of the muscular coat of the arterioles pointed out by Ludwig, Traube, Johnson, and others, as well as the other minute structure of the chronically-contracted kidneys.

At this meeting of the Society, a committee was also appointed to which was referred the subject of the so-called "ovarian cell," pointed out by Dr. Drysdale. The committee was directed to make comparative investigations of ovarian, serous, cystic, and other fluids with a view to determining the existence of a cell sufficiently distinctive to be called "ovarian cell." The President appointed Drs. Tyson (chairman), Bertolette, Richardson, Jenks, Mears, and Willard, with power to increase this number.

REVIEWS AND BOOK NOTICES.

TREATISE ON THERAPEUTICS: COMPRISING MATERIA MEDICA AND TOXICOLOGY, WITH ESPECIAL REFERENCE TO THE APPLICATION OF THE PHYSIOLOGICAL ACTION OF DRUGS TO CLINICAL MEDICINE. By H. C. WOOD, JR., M.D. J. B. Lippincott & Co., Philadelphia, 1874.

The want which this work of Dr. Wood is written to supply is a very real one, as any one must have felt who is constantly asked by students for the best text-book in therapeutics, and who is as constantly constrained to reply that there is none in English wholly or approximately satisfactory. The books written by those whose lives have been passed in the practice of medicine, and which are chiefly of a clinical and so-called practical character, seem very meagre to the physiologist, and must always be open to the very grave objections urged against supposed therapeutic facts based upon the usual clinical observation alone. Such are the works of the elder Dr. Wood, Waring, and Stillé. The latter, although by no means rejecting experimental data, has not kept pace with recent investigation, and fails in that appreciation and co-ordination of isolated facts which we have a right to expect in a systematic treatise. It has been, however, on the whole, the best work on the subject.

The little work of Dr. Ringer is exceedingly attractive from its conciseness, the positiveness with which its views are announced, and the apparently great confidence which the author places in the practical

resources of therapeutics. But the experienced physician can hardly sympathize with the author's enthusiasm, and the student who accepts his views without a very liberal allowance of skepticism is preparing for himself a future of disappointment. Besides this, it is entirely devoid of systematic arrangement, a deficiency which, notwithstanding all that may with truth be said of the impossibility of a scientific classification, is a very great one.

Nothnagel's book has been, since its recent (1870) appearance, by far the best one; and had there been a good translation it would have been at once recommended by the writer to all his students, as the German original now is to those who can read it. And from this position he is not yet prepared to displace it.

Dr. Wood in his preface fully recognizes the perplexities and contradictions which beset the older method of therapeutic investigation, and desires to avail himself of experimental results so far as possible. He says that he is surprised to find how much has been done in this direction; and we must congratulate him upon the success with which he has searched in the literature of experimental pharmacology, which is indeed extensive.

He says, "The plan of the present work has been to make the physiological action of remedies the principal point in discussion. A thoroughly scientific treatise would in each article simply show what the drug does when put into a healthy man, and afterwards point out to what diseases or morbid processes such action is able to afford relief."

"Unfortunately, in the great majority of cases, our knowledge is not complete enough for this, and the clinical method has to be used to supplement the scientific plan."

We cannot altogether agree with him here: pathology is not yet sufficiently advanced, if it ever will be, to make an *immediate* application of experimental pharmacology of practical use, no matter how perfect the latter science may be; and we think it a mistake, and one calculated to retard the advance of therapeutics, to oppose experiment to "clinical observation." Granting that the latter method of investigation is exposed to almost innumerable chances of error, from which the former is free, and acknowledging that a vast amount of so-called clinical observation is utterly untrustworthy, it is not necessarily so. If it is a "pursuit of knowledge under difficulties," yet a measure of knowledge, at least, may be attained by disinterestedly seeking for it; and when it is attained it is directly useful. The foundation of science is not in the subjects investigated, nor in the special means of investigation, but in the scientific mind, the logical spirit in which the work is carried on.

Dr. Wood should remember, too, that disagreements between various experimenters, not only as to the theories, but also as to the facts, in experimental observations on drugs, are by no means unknown, and that physiology is far from being a complete science, even in regions which have been industriously explored.

However much we are inclined to disagree with the author's preliminary views, we do not feel so much disposed to find fault with the way in which he has carried out his views. No writer on this subject can possibly get rid of clinical results if he wants to; and the author has not attempted it.

Lists of antispasmodics and alteratives, the latter including sarsaparilla, guaiacum, sassafras, and dandelion, show that he thinks the opinions of his predecessors worth mentioning, even if he does not agree with them.

The classification seems not altogether satisfactory in many points; but, as the writer is obliged to say the same of every one that he has yet seen, including his own manufacture, it is hardly worth while to do

more than mention, for instance, that all the alkaloids of opium cannot properly be included under the head of analgesics; that the mydriatic action of atropia is not its principal one; that the division of emetics simply into vegetable and mineral ignores a more important physiological distinction; and that drugs like epispastics, which act only through the nervous system without entering the blood, ought not to be placed in the same division with those which, like diuretics, are absorbed and re-secreted,—some of them at least having a decided effect in the excretion of solids, rendering probable an action upon the general metamorphosis of tissue.

In the body of the work, Dr. Wood has given a brief, but, for his purposes, sufficient, description of the drugs discussed. Then we have a statement of physiological and clinical facts, so far as they contribute to a knowledge of the *modus operandi* of the drug; and, in conclusion, a summing up of actual results, indications for use, and methods of administration. The poisonous action is stated; since it may not only contribute to a knowledge of the mode of action, but because the physician may have to combat toxic effects, or inform a court in criminal cases.

The author has—very wisely, we think—avoided on the one hand long theoretical discussions about words, though not neglecting such a statement of theory as may best harmonize the facts; and, on the other, such absolutely valueless but apparently “practical” statements as that Dr. Weissnicht of Mudfog “deems sassafras a sovereign remedy for peritonitis,” or that “Dr. R. Pipiens, of Barking Hollow, has cured a hundred cases of croup (many of which were supposed to be membranous) with a syrup of *symplocarpus fetidus*.”

If it should seem to some critics, as it probably will, and as the preface leads us to expect, that the clinical side is somewhat neglected for the experimental, it should be remembered that this condition is precisely the opposite of that which obtains in nearly all the works on therapeutics already in use, and that this is strong where they are weak. Still further, if this book is to be used, as it will be, for a text-book, the student begins with that part of the subject which is the more accurately known, and proceeds thence to the practical application of his knowledge,—being thus provided with a basis for intelligent appreciation and criticism before beginning his observations on the practice of his clinical teachers. No one can deny that it must contribute immensely not only to the welfare of the patient, but also to the comfort of the practitioner, that the latter should begin his professional life with a clear understanding of the mode of action of drugs, and a rational skepticism as to their therapeutic value, rather than encouraged by vain promises of success which can never be fulfilled, and take refuge, after years of random attempts and disheartening failures, in the skepticism of ignorance.

We think that this work will be a very valuable one to teachers and students, as well as to those who wish to have at hand some statement of the latest physiological and experimental investigations without going through the labor necessary to find them in the periodical literature of the last two or three decades.

The book seems very free from misprints and misspelling, and the neatness of its dress is sufficiently guaranteed by the names of the publishers.

ROBERT T. EDES.

HARVARD UNIVERSITY MEDICAL DEPARTMENT.

ANNUAL REPORT OF THE SUPERVISING SURGEON OF THE MARINE HOSPITAL SERVICE OF THE UNITED STATES FOR THE FISCAL YEAR 1873. By JOHN W. WOODWORTH, M.D.

This report gives the laws regulating the marine hos-

pital service, the progress of the re-organization of the same, the details of the year's working, and some papers of general professional interest. Among the latter we would especially notice those on yellow fever, one of them containing a very elaborate table giving the localities in which yellow fever has appeared since A.D. 1868, their elevations above the sea, and the duration and time of the epidemics, as well as the mortality.

We notice that there were treated during the year in the various hospitals of the service, at an average cost of one dollar per day, 12,697 seamen, and the hospital-money collected from the seamen was \$335,845,—facts which show the great importance of the service.

GALVANO-THERAPEUTICS. Lindsay & Blakiston, Philadelphia, 1873.

This little book of sixty-five pages, the name of whose author, strangely enough, does not appear on the title-page, is, we believe, a revised reprint of a report made to the Illinois State Medical Society in 1873 by Dr. Prince. It is by no means a complete treatise on the subject, but contains interesting, although dilute, reports of the use of the remedy in various cases. Those who wish complete libraries will of course purchase the memoir, but we do not think it can in any way supply the place of larger and more complete works. We notice that tendency to let loose the imagination, which seems an inherent property or quality of most medical electricians. Thus, we are told in inflammations to apply the negative pole to the inflamed spot, so as to diminish the oxygen in the part, and thus “starve the phlogosis.”

GLEANINGS FROM OUR EXCHANGES.

SPECIMEN OF FATAL CAUTERIZATION OF LARYNX AND ŒSOPHAGUS.—Dr. Jacobi (*N. Y. Obstet. Soc. Trans.*, December 2, 1873) exhibited the digestive organs of a child, nine months of age, which had been taken ill with what had been reported as croup. The medical attendant advised cauterization of the larynx, and attempted it with the solid stick of nitrate of silver: the stick broke, however, and the child swallowed the detached portion. The child died, and the specimen removed at the autopsy was sent to Dr. Jacobi, with the above imperfect history. The epiglottis, upper vocal cords, the whole interior of the larynx, and the upper portion of the trachea, appear considerably reddened and hyperæmic, which, however, may be partly due to imbibition: at all events, there were no traces of croup, but only the indications of a simple laryngeal catarrh. The action of the nitrate of silver was not localized, but the whole laryngeal mucous membrane was equally injected and hyperæmic. The Œsophagus was injured by the caustic to the extent of one inch at its commencement, a distinct eschar being visible. The stomach shows no injury in its cardiac portion, the piece of caustic having followed the dependent position of the organ and lodged near the pylorus, where a solid piece of the stick of nitrate of silver is still to be seen, surrounded by a thick layer of albuminates, and imbedded in the coats of the stomach; there is no secondary local inflammation about this spot, an observation agreeing with the acknowledged action of lunar caustic.—*Amer. Jour. Obstet.*, February, 1874.

PUERPERAL THROMBOSIS (*The Lancet*, February 28, 1874).—At a meeting of the Obstetrical Society of London, the above subject was discussed.

Drs. Playfair and Hayes pointed out that thrombosis had a wider application than was commonly given

it, as a cause of disease and of sudden death in puerperal women. Attention has been chiefly limited to only one of the manifestations of this disease, on account of its tangible symptoms,—phlegmasia dolens, which is, however, dependent upon the same conditions as ante-mortem plugging of the pulmonary artery, the clots being produced by the changes wrought in the blood by the pregnant state or its accidents, such as flooding, septicæmia, etc. Dr. Taylor thought there were three points worthy of notice: 1, it appeared that the patients were suddenly found to be at the point of death before any danger had been apprehended; 2, in those cases which were examined after death a firm laminated clot was discovered, evidently not of very recent formation; and 3, in those cases in which a stethoscopic examination was able to be made, some abnormal sound was discovered at the base of the heart. He would suggest, therefore, that if the heart-sounds were subjected to examination during the puerperal period, either as a matter of routine or, at any rate, more generally than they usually are, in all cases, or at least in those in which thrombosis is prone to occur, as after hemorrhage, the danger might in some cases be foreseen, and by suitable treatment be lessened or averted. Dr. Routh extolled the efficacy of liquor ammoniæ in the prevention of thrombosis, or in the removal of clots already formed.

TREATMENT OF PITYRIASIS RUBRA (*The Lancet*, February 28, 1874).—Dr. Tilbury Fox believes that in cases of pityriasis rubra—hyperæmia of the skin and exfoliation of the cuticle—the free use of diuretics is called for, especially in cases which come under observation at an early date, before the hyperæmic state of skin has given rise to secondary alteration, such as infiltration into the tissues. It is an established rule in renal therapeutics to stimulate the skin to increased action in cases where the kidneys are congested, or in other conditions in which it is desirable that they should be given rest from work. In the case of a hyperæmic state of skin, where this hyperæmia is not removable by local remedies, and where it is extensive, it is likewise desirable to stimulate the kidneys to increased activity, to relieve the skin of its work,—to give it rest.

Dr. Fox uses a diuretic mixture composed of half a drachm each of acetate and bicarbonate of potassium, one drachm of spirit of juniper, and one ounce of infusion of calumba, for each dose, three times daily. The skin is soothed by oily inunctions, and perchloride of iron is administered internally to act as an astringent to the weakened cutaneous vessels.

DANGER OF INTRA-UTERINE INJECTIONS.—The *Gazette de Foulon* gives the details of two cases, which show that while intra-uterine injections are energetic agents in modifying the conditions of this mucous cavity, they should only be employed with caution.

In one case, though the patient had become enfeebled by repeated hemorrhage, she endured, without suffering inconvenience, two injections of the uterine cavity. A third, consisting of a weak infusion of chamomile and diluted perchloride of iron, was succeeded by death in thirty hours after decided symptoms of subacute peritonitis. The mucous lining of the uterus and right Fallopian tube, and the adjacent peritoneal surface, were found, after death, covered with an ink-black clot and presenting unmistakable evidences of inflammation.—*Medical Examiner*.

CONGENITAL DEFORMITY FROM IMPRESSION UPON THE MIND OF THE MOTHER (*The North-Western Med. and Surg. Journ.*, March, 1874).—Dr. Franklin Staples reports the following case. A laborer, working in a stone-quarry, had his right hand badly crushed by a falling derrick. The mangled part was amputated, but

the loss of the thumb and forefinger and subsequent contraction of the tendons resulted in an ugly deformity. At the time of the accident, and for some months afterwards, the man resided in a boarding-house, the mistress of which was pregnant. While he was ill she nursed him and dressed his hand, although with a strong feeling of dislike and almost of disgust, and subsequently the frequent sight of the stump greatly annoyed her.

In due time she was delivered of a healthy female child, well formed and fully developed in all respects, with the exception of its right hand, the three middle fingers of which were absent. The general appearance of the two deformities was remarkably similar. Both parents were healthy; their other children had been well formed; and no instance of congenital deformity had ever occurred in their families.

SCIRRHUS OF THE MESENTERY (*North-Western Med. and Surg. Journ.*, March, 1874).—Dr. Staples reports a case diagnosed to be scirrhus of the mesentery, involving duodenum and pylorus. Gerinan, male, aged 50, sick four months, pain in epigastrium, frequent vomiting, obstinate constipation, emaciation, cancerous cachexia, tumor three inches in diameter, circumscribed and movable, nearly in centre of epigastrium. The patient had worked in a sawmill, and had worn a tight leathern belt for years, instead of suspenders. Dr. Staples had known another case of scirrhus of the pylorus in a man who had worn a tight belt, and another of cancerous disease of the mesentery in a patient who had for several years worked in a shingle-mill, where he was compelled to lean over the bench of his machine, bringing a constant pressure to bear across the abdomen.

POSTURAL TREATMENT FOR EXTENSIVE DISTENTION OF THE INTESTINES WITH GAS (*Chicago Medical Journal*, March, 1874).—Dr. Chas. T. Parkes recommends that what he terms the "postural treatment" should be tried in all cases of tympany, especially in those complicating gestation. A large enema should be given, so as fully to empty the lower bowel; the patient should then be turned with the face downwards, so as to throw the weight of the body on the distended abdomen; the thighs being flexed upon the abdomen, the patient should be directed to make straining efforts, which are usually followed by the escape of large quantities of gas.

MISCELLANY.

CREMATION.—The subject of cremation is again taken up by Sir Henry Thompson in the pages of the *Contemporary Review*. In this article he replies to various criticisms that have appeared in different journals, and gives a detailed account of the process he would suggest as most appropriate for the object in view. Sir Henry states, and it is certainly a somewhat remarkable fact, that the only formal opposition to cremation has been made by the present medical inspector of burials for England and Wales, Mr. Holland; and in reply to the observations of this gentleman, Sir Henry refers to the evidence obtained by Drs. Southwood, Smith, Waller, Lewis, and others, in regard to the large amount of gases produced in the decomposition of the body, and the impregnation of soil, water, and air to a considerable distance. Such impregnation by the dead, and consequent danger to the living, cannot, we presume, be questioned for a moment, and is fully borne

out by the statements of Mr. Bowie and the general experience of the profession. We must also fully endorse Sir Henry's remarks in regard to the elimination of ammonia, or at least of carbonate of ammonia, from decomposing animal tissues, and are at a loss to understand how any doubt can exist about the point.

Turning to the second part of Sir Henry Thompson's essay, he remarks that he has personally superintended the burning of three bodies of animals, one weighing forty-seven pounds, another one hundred and forty pounds, and a third no less than two hundred and twenty-seven pounds, with the most satisfactory results, the residue in the first instance weighing only one and three-fourths pounds, and the second four pounds. In the last case the body was placed in one of Dr. Siemen's furnaces, the interior of which was heated to about 2000° F. The inner surface of the cylinder, which was about seven feet long by five or six feet in diameter, was smooth, almost polished, and no solid matter but that of the body was introduced into it. The gases, which were at first abundantly given off, passed through a highly-heated chamber, among thousands of interstices made by intersecting firebricks laid throughout the entire chamber lattice-fashion, in order minutely to divide and delay the current, and to expose it to an immense area of heated surface. By this means they were rapidly oxidized, and not a particle of smoke issued by the chimney. No second furnace was therefore in this instance requisite, though under certain circumstances the products of combustion might be transmitted through another, and the fumes from this into a third, and so on, each being made available for the combustion of one body. The process was completed in fifty-five minutes, and the ashes, which weighed about five pounds, were removed with ease. Sir Henry meets the objection that has been raised to the practice of cremation, that it will lead to an increase of crimes of poisoning, by suggesting that a public verifier of the cause might be appointed, whose duty it should be to ascertain and certify the cause of death, whilst the stomach might be kept for some years. In reference to the expense, he still thinks it would be far within the present cost of a funeral. As regards ourselves, we have already expressed our opinion that it is an eminently satisfactory mode of disposing of the dead,—safe, speedy, wholesome, and economical; but we rather doubt whether ancient custom and popular prejudice can be so easily overcome and altered as Sir Henry Thompson appears to believe.—*London Lancet*.

UTILIZATION OF SEWAGE.—The following facts with regard to the utilization of the sewage of the city of Paris are taken from the official returns. At Clichy, a bend of the Seine forms a sandy, level peninsula of some 5000 acres. The barrenness of this peninsula is proverbial, and hence it was on this land that a portion of the city sewage was first directed, with a view to put the utility of this kind of fertilization to the severest possible test. The preliminary works were begun in 1868, and completed in May, 1869. From that time

between 5000 and 6000 cubic yards of the sewage have been raised daily by engines of forty-horse power and centrifugal pumps, and of this two-thirds were received into tanks for chemical manipulation, the remainder being applied to a piece of land twelve or fifteen acres in extent. At the end of several months, the results of this experiment upon a naturally poor soil were such that the neighboring farmers asked to be included in the benefits derived from the sewage. Owing to the extreme permeability of the soil, 20,000 cubic yards of sewage could be annually absorbed per acre, and the farmers obtained crops of 70,000 pounds of cabbages, 60,000 pounds of carrots, and 150,000 pounds of turnips. All land suitable for irrigation rose in value. No evil effects on the health of the inhabitants could be detected, and a village sprang up around the works. A Parisian perfumer established his manufactory on the outskirts of the irrigated land, and obtained a supply of the sewage-water for his gardens of aromatic herbs, more especially of peppermint. It is worthy of note, in this place, that the finest mignonette of Covent-Garden Market, London, has long been grown from sewage-irrigated soil.—*Popular Science Monthly*.

DR. LOUIS A. DUHRING was recently elected Lecturer on Dermatology in the University Hospital.

DR. H. C. WOOD was also appointed to the position of Clinical Lecturer on Diseases of the Nervous System, and Dr. James Tyson Lecturer on Pathology and Histology, in the same institution.

DEATH OF DR. FORBES WINSLOW.—Dr. Winslow was born in London, in 1810. He began his medical studies in New York, took the degree of M.D. at King's College, Aberdeen, and became a member of the Royal College of Surgeons, London, in 1835. His first published works appeared in 1831, since which time he has made numerous important contributions to the literature of medicine, chiefly in the department of nervous and mental diseases. His most valuable work in this line, "The Obscure Diseases of the Brain, and Disorders of the Mind," was published in 1860, and has since passed through several editions. He died in London on March 4, 1874.

NOTES AND QUERIES.

[THE following extract from a letter to Dr. T. G. Morton, of this city, by Lawrence M'Cully, Esq., of Honolulu, in regard to leprosy, has seemed to us to be well worthy of a place in this department of the *Times*.—ED. P. M. T.]

The question of our exposure to the disease came to us, the foreign community, within the year, with terrible personal interest. While the new government of Lunalilo was energetically prosecuting the sad business of collecting the lepers, separating them from their families, and deporting them to perpetual seclusion, it was rumored that two or three white men of respectable station had the disease. One was M. C—, a French gentleman, say of 55 years, a resident here for perhaps ten years. He had come here with his wife and family; had been a widower for five years. He had suspicious blotches about the temples, or below, and a thickening of the lobes of the ear. Of course he disclaimed it; if I remember, he passed some medical examination; he continued in public. The signs of it were such that the public feared communication with him. A further examination was insisted on, and, being stripped, he was found covered with an unmistakable leprous eruption, was confined in the receiving hos-

pital, and subsequently, having made his own arrangements to be received by the French government at Tahiti, was transported thither, and has since been taken to France. He claimed at first, stoutly, that he had not exposed himself by illicit connection, and that he must have got his disease from his washed clothes, or otherwise innocently; and we thought, from his age, his family circumstances, etc., that it was so, and just that was what frightened us. It was not doubted that men of promiscuous licentious habits exposed themselves to something worse than venereal, but if wholesome, respectable, and moral men, as well as women and children, were liable to take the disease, we must flee the country at any sacrifice of property. But investigation relieved us by finding where M. C— got his disease, and confronting him with the very woman, who had become a developed leper.

Then there was the case of Mr. B—, "Judge B—," published a short time since in the California papers. Mr. B— was well known to all of us here,—a family man, beyond middle life when he left here; a church-member, in the odor of respectability; no rumor tainted his name; a man of fastidious personal neatness, and refined tastes.

Some time after he left the kingdom, to live in San Francisco, we heard that he had a mysterious disease; leprosy was sometimes hinted. He still kept in public, holding his office of Commissioner in Bankruptcy till shortly before his death. We have no doubt here, and I understand there is now no doubt there, that it was leprosy. How did he get it? We must think that, all unsuspected, he yielded to temptation, and suffered in this terrible and exceptional way. Rev. Mr. Damon told me that some one, whose name he did not give me, told him that he knew that such was the fact, mentioning the house itself where Mr. B— had resorted.

But three or four foreigners have been found with leprosy; all of them of a class as liable to take it as the natives, because they live in about the same way. One was a German blacksmith,—my nearest neighbor, in locality; my residence is out of town. He used to say that he feared he had the leprosy. This was some six years ago, when there was less alarm about the matter. For some time he had enlargement of the ears, and some leprous appearance on his forehead. On a final examination, for which he presented himself, it was settled that he had the disease, and should go to Molokai. He was allowed time to settle his humble affairs, and went, now five years ago. I have learned that the disease has progressed so that his fingers and toes have dropped off. His wife, a native woman, followed him there, and still remains, and, as yet, does not herself show leprosy. His five children were left behind, and show no symptoms of it. Three of them, boys, of 11 years and under, remain in my neighborhood, and are daily about my house,—poor little waifs!—living from my kitchen, as nice-looking as any native children.

One of the foreigners who has the disease is Williams, an elderly man, a mason by trade. I saw him at the Kalihi Receiving Asylum, at the only visit I have made there. The disease appeared externally on him, in his ears, hands, and forehead. In some conversation, he appeared very well; said that he was careful to avoid giving contact to any of his friends who visited there; that he was deriving some benefit from medicine he was taking experimentally. He showed us his son, a small boy, among the lepers, who was a pitiable spectacle. His wife (a native) had died of the disease. My impression is that all their children have it. Williams said it first appeared in the family after they had all been many hours in the sea, from the capsizing of a little inter-island coaster, when this Hawaiian woman for half a day assisted her husband and sustained her children, swimming to the shore.* It is understood that the general cachexy of the Hawaiians has greatly promoted the spread of the disease,—indeed, is almost a condition of it. You are aware of the great diffusion of the syphilitic taint among them: this is aggravated by neglect, uncleanly habits, ill-ventilated houses, etc., and especially by the use of *awa*, which itself depraves the blood, and makes the user of it look like a white-scaled leper, and diffuses any contagious thing they may have, by their mode of preparing and using it, which is by having persons to chew it, and, collecting the saliva (which it excites in quantity) in a bowl, diluting it, perhaps, with water, all drink from the same. So, too, their custom is to draw several whiffs from the pipe, and pass it on through the circle, carrying from lip to lip whatever disease any one person may have.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Having made more than one attempt to medicate the fundus of the uterus, as suggested by Dr. William Goodell in his articles published in the *Medical and Surgical Reporter*, I cannot help expressing my conviction that the medicine used, be it tincture of iodine, or what not, is entirely wiped off as it passes through the cervical canal. If the gentleman can offer proof that he does get his medicine in contact with the mu-

cous lining of the fundus, I have nothing more to say. In my humble opinion, the benefit derived is due to the direct effect upon the cervical canal, for I feel sure that when the attempt is made to introduce a probe, wrapped with cotton, dipped (we will say) in the tincture of iodine, through the cervical canal to the fundus, the cotton is squeezed dry, so that he *does* reach the fundus, but with a pledget of cotton only stained with iodine, from the point of which (the pledget) I fail to see how he can medicate.

Yours, very truly,

March 25, 1874.

SUBSCRIBER.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

A MEDICAL man practising in Nebraska has just written me, in a private letter, an account of an accident the possibility of which may not have been familiar to all surgeons. Perhaps, therefore, it ought to be made useful by publication.

Having to treat an old man of 83, for distressing retention of urine, produced by enlarged prostate, along with stricture of the urethra, he succeeded, with difficulty, in introducing an elastic catheter into the bladder. While, however, he was withdrawing the stilette, the catheter *broke in the middle*, leaving a considerable portion in the bladder. An operation was performed successfully for its removal. About fifteen days afterwards the patient's death occurred,—although not referred, by the gentleman giving the account, to the accident, or to the operation following it.

The catheter employed appeared to be sound, but was probably old, and had been used but once before.

Very respectfully,

HENRY HARTSHORNE, M.D.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

1400 PINE STREET, PHILA., March, 1874.

THE Annual Session will be held in the city of Easton on Wednesday, May 13, 1874, at 3 P.M.

The Address in Surgery by Thomas M. Drysdale, M.D., Philadelphia.

The Address in Medicine by T. H. Helsby, M.D., Luzerne.

The Address in Obstetrics by William B. Atkinson, M.D., Philadelphia.

Report of the Committee on the Regulation of the Practice of Medicine and Surgery. Chairman, Dr. R. L. Sibbet, Cumberland.

On Education of Deaf-Mutes. Chairman, Dr. L. Turnbull, Philadelphia.

On Care and Treatment of Insane Criminals. Chairman, Dr. John Curwen, Dauphin.

On Compulsory Vaccination. Chairman, Dr. Benjamin Lee, Philadelphia.

Secretaries of County Societies are requested to forward their lists of officers and members, with the post-office address of each member, to the undersigned, at their *earliest convenience*.

WILLIAM B. ATKINSON,
Permanent Secretary.

WE have received a copy of the CONSTITUTION AND BY-LAWS OF THE ALUMNI ASSOCIATION OF THE ALBANY MEDICAL COLLEGE, and have been requested to call attention to the following paragraph in an accompanying circular:

"Your attention is therefore asked to the subject, and a careful perusal requested of the Constitution and By-Laws—adopted by the Association—which accompany this circular. The Executive Committee desire that these may be placed in the hands of every graduate, and also propose making a complete catalogue of the Alumni. It is therefore necessary that their present residences be ascertained, and to this end all graduates are requested to send to the Secretary, *without delay*, their present addresses and also those of other graduates with whom they may be acquainted, especially of those in their immediate vicinity."

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 24, 1874, TO MARCH 30, 1874, INCLUSIVE.

PETERS, D. C., SURGEON.—Assigned to duty at Nashville, Tennessee. S. O. 43, Department of the South, March 21, 1874.

WEBSTER, WARREN, SURGEON.—Assigned to duty at Alcatraz Island, California. S. O. 29, Department of California, March 16, 1874.

HEIZMANN, C. L., ASSISTANT-SURGEON.—Relieved from duty with Sioux Expedition, and to resume his duties as Post-Surgeon at Fort McPherson, Nebraska. S. O. 42, Department of the Platte, March 23, 1874.

* Williams has since gone to Molokai.

SATURDAY, APRIL 11, 1874.

ORIGINAL COMMUNICATIONS.

FETID CORYZA.

BY J. SOLIS COHEN, M.D.,

Lecturer on Laryngoscopy and Diseases of the Throat and Chest, in Jefferson Medical College.

(Continued from page 419.)

TREATMENT.

THE treatment of a case of fetid coryza will depend upon its nature. When due to the presence of a foreign body, a rhinolith, or a morbid growth, the removal of the exciting cause will cure the discharge. In cases with constitutional taint, systemic treatment is required. The treatment of this condition, in fact, is simpler in principle than in practice; but it is always tedious, and often unsatisfactory. Palliation of the severer symptoms and diminution of the fetor can almost always be effected, but a thorough cure often requires months of persistent treatment; in some instances seeming almost unattainable, and in others, quite so. When the larger bones are diseased, and it is impossible to get access to them, the condition will continue for years; dead bone being exfoliated splinter by splinter, and fresh involvements becoming new sources of evil as older ones are undergoing amelioration.

In scrofulous cases we can endeavor to improve the tone of the constitution by resort to systemic remedies, such as cod-liver oil, quinine, and iron, the preparations of iodine, arsenic, and so on; and we may thus repress increase in the malady, even if we fail in restraining it. The administration of cubebs, preferably, in my own practice, in doses of fifteen to twenty drops, or more, of the oleoresin on sugar, after meals, will sometimes diminish the copiousness of the secretions to a certain extent, and modify their character by the local influence of the drug in its elimination through the mucous membrane of the nasal tract.

The decidedly syphilitic cases, when not so far advanced as to be irremediable, are much more manageable under systemic medication than are the idiopathic and scrofulous cases. Here small doses of the bichloride of mercury, with the free use of the iodide of potassium, are just as serviceable as in other forms of constitutional syphilis, especially if the general vigor of the patient has not been greatly impaired. If the general health is poor, a generous allowance of nutritious diet, assisted by a tonic course of treatment, will be necessary before beneficial results can be expected from specific remedies.

All forms of fetid coryza require local treatment. The parts should be frequently cleansed, and topical remedies assiduously applied. Without preliminary cleansing, local remedies are of little avail: they become entangled with the secretions to a certain extent, and cannot exert that good effect upon the parts which they exercise when applied upon a clean surface.

As mentioned in connection with cleansing the parts preparatory to examination, we use for this purpose the nasal syringe, applied anteriorly and posteriorly, and the continuous nasal douche; employing the medicinal articles already enumerated. These ablutions are by no means to be neglected, but should be attended to as punctually and as scrupulously as the patient attends to other wants of nature.

The local applications for remedial purposes consist of solutions, powders, vapors, and unguents, brought in contact with the parts by suitable appliances. When ulcerated surfaces can be reached by instruments introduced within the nostrils or behind the palate, they should be regularly touched by the sponge, cotton wad, or hair pencil, loaded with a solution of nitrate of silver, sulphate of copper or of zinc, carbolic acid, chromic, nitric, or muriatic acid, or the acid nitrate of mercury, as the case may seem to demand. Dead bone, where accessible, should be removed by the forceps, assisted, if need be, by the knife or scissors. Too much force should not be exerted in the endeavor to remove dead bone. It is better practice often to use frequent traction from side to side with forceps, in a sort of dislodging motion, so as to loosen the pieces of dead bone, and thus gradually render them sufficiently movable to be extracted without much physical effort. If the bone is too large for removal through the nostril in mass, it may be crushed between the blades of strong forceps, or divided by cutting-pliers, and be extracted piecemeal. In many instances the dead bone may be removed through the mouth by means of curved forceps passed up behind the palate.

The contact of the opposing surfaces of mucous membrane can often be overcome by the daily interposition, for an hour or more at a time, of strips of compressed sponge, or of tubes of laminaria; mechanical appliances which compress the parts as they imbibe moisture from the secretions, thereby favoring absorption of the products of submucous infiltration. Where hypertrophied or exuberant mucous membrane exists, and where internal compression is insufficient to enlarge the passage for the free ingress and egress of air and the free discharge of the secretions, it is good practice to twist off portions of the membrane with delicate forceps, so that cicatrization of the irregular edges of the wound may enlarge the passage. The free bleeding accompanying this procedure exerts a salutary influence upon the parts; and though the operation is very painful, it is so efficient in its relief that the patient will readily submit to it again and again, for the sake of the ease it affords in respiration afterwards.

The solutions used by douche or injection may contain chlorate of potassa, alum, creasote, or carbolic acid, permanganate of potassa, chloride of lime, or similar substances, which, in addition to their local action on the parts, tend to control fetor. Or we may use special injections or sprays of nitrate of silver, sulphate of zinc and of copper, the sulphocarbolates of zinc or lime, bichloride or iodide of

mercury, chloride of zinc, chloride of lime, and the like. These injections should be employed at least twice a day, night and morning, and, where practicable, three and even four times a day; and they should always be preceded by the use of the douche for cleansing-purposes. They should be used in weak dilution at first,—say two or three grains to the ounce,—and be gradually increased in strength as tolerance of them is manifested; care being taken that none of the solution is swallowed by the patient, on the one hand, and that too free use of remedies which act promptly on the system be not made, on the other; for the nasal mucous membrane readily absorbs certain remedies, and the proximity of the olfactory filaments to the nervous centre favors the systemic effect of others. This latter fact is often utilized to subdue the pain in the frontal region, by the local application of an ointment containing three or four grains of morphia, or one or two of the extract of stramonium, to the ounce; not more than the volume of a pea being used at a time.

A solution of the chloride of lime was used in this city, with great success, by Prof. Horner, who injected each nostril twice a day with a solution containing a teaspoonful of the chloride of lime in a wineglassful of water. This practice is not much in use to-day, but it deserves to be. A somewhat similar formula, from which I have sometimes obtained very satisfactory results, contains from thirty to sixty grains of the chloride of lime to the ounce of the decoction of krameria; of which two or three drachms, or more, diluted with an equal quantity of water, are injected into the nostrils night and morning, immediately after the use of the douche. Sometimes the parts will not bear a solution of this strength, and it must be diluted accordingly. When the remedy excoriates the external tissues, as it will do sometimes, its use must be suspended or its strength reduced, as may seem most judicious. Perhaps a preliminary coating with colodion will prevent this excoriation, but I have never tried it.

Glycerin is sometimes of great service as an injection, particularly in scrofulous cases. Being bland and unirritating, its affinity for moisture of all kinds facilitates the separation and removal of the secretions, inspissated crusts, and detached fragments of dead bone. The addition of iodine, in the proportion of a grain or two to the ounce of glycerin, is sometimes advantageous.

Prof. Trousseau relied greatly upon certain medicated powders to be snuffed up by the patient twice or thrice a day, after having cleansed the nostrils as thoroughly as possible. His principal formulæ were calomel, a drachm to the ounce of sugar, and red precipitate, forty grains to the ounce of sugar; their use being regulated in accordance with the irritation produced. Another favorite powder, with which he was very successful, was composed of bismuth rubbed up with equal parts of Venetian talc, and this, on account of its innocuousness, was used as freely as was desired.

Camphor, tannin, cubebs, and other substances, separately or in combination, have been used in a

similar manner; some practitioners mixing them with two or three times their bulk of Scotch or Welsh snuff. Various mechanical appliances are in use for the purpose of injecting the powders upon the parts.

Citrine and other ointments, more or less diluted, are sometimes used locally after thorough cleansing; being applied to the parts by the little finger, a hair pencil, or a cotton wad on the end of a wire.

The principal remedies used in the form of vapor are preparations of mercury, evaporated over a spirit-lamp, the fumes from which are drawn by inspiratory effort through the nostrils. The fumes of muriate of ammonia from the heated salt itself, or in a nascent state from commingling of the vapors of muriatic acid and strong aqua ammoniæ, are also used a great deal in the scrofulous cases, both for local and constitutional effects.

With all these resources at command, we are able to improve the condition of patients affected with fetid coryza, and place them under the most favorable conditions for the cure of whatever affection has given origin to this loathsome catarrh.

CAN "NUTRITIOUS ENEMATA" BE DIGESTED AND ASSIMILATED?

BY G. TROUP MAXWELL, M.D.,

New Castle, Delaware.

THIS article, or its material points, was published in the Savannah (Ga.) *Journal of Medicine*, November, 1866. It was so badly printed, and contained so many typographical errors, as to be scarcely intelligible to myself, and for that reason I republish it in the *Medical Times*.

The question whether food, in the form of "nutritious enemata," injected into the rectum, can be digested and assimilated in the large intestines, is one of not merely speculative interest, but involves, besides, points of practical importance; for the speedy, successful treatment of most of the lesions of the stomach and small intestines and of their glandular auxiliaries in the process of digestion may be much more easily accomplished when, in support of the judicious application of appropriate remedies, absolute rest from the performance of their function as digestive organs can be enforced.

I seriously doubt the efficacy of nutritious enemata, and in discussing the question shall endeavor to maintain—1, that digestion is a necessary preliminary to assimilation; 2, that digestion is begun and completed in that part of the alimentary canal which is above the ileo-cæcal valve; and 3, that the large intestines are not digestive organs, and neither do nor can perform the function of digestion.

That digestion is a necessary prerequisite to assimilation or nutrition, is a postulate which will require little or no argument to prove, as no one will seriously question or deny it. The universality of the existence of organs suitable for the performance of that function in animals from the lowest to the highest in the scale of being, is conclusive evi-

dence upon the point. An important distinction between the vegetable and animal kingdoms is that, whilst the former find their food consisting of inorganic elements in a fluid or gaseous state, in simple form, ready for absorption, the latter receive theirs as compound organized substances, which must be reduced, liquefied, and vitalized, and thus prepared for assimilation. To effect this result, organs more or less complex, according to the nature of the food to be acted upon, with certain secretions which are common to all animals, are provided. In the Graminivora a large and more complex mechanism is found, the function of which is to extract from the large bulk of food received into it the comparatively small amount of nutriment it contains; whilst in the Carnivora, the proportion of nutritious ingredients of the food being much larger, and the reduction and liquefaction of it much more easily effected, a set of organs proportionately small and simple is found. Whether the organs of digestion be large and complicated, or small and simple, certain secretions, known to be digestive fluids, are always present, and their essential importance in the digestive process has been demonstrated.

In support of the view that digestion is completed when the food, in its passage through the alimentary canal, reaches the ileo-cæcal valve, there is no lack of testimony. Dr. Dalton, in his great work on Physiology, says, "Digestion of the food is not a simple process, but is made up of several different processes, which commence necessarily in different portions of the alimentary canal. In the first place, the food is subjected to the physical operation of mastication and ensalivation. Reduced to a soft pulp and mixed abundantly with saliva, it passes secondarily into the stomach; here it excites the secretion of gastric juice, by the influence of which its chemical transformation and solution are commenced. If the meal consists wholly or partially of muscular flesh, the first effect of the gastric juice is to dissolve the intervening cellular substance, by which the tissue is disintegrated and the muscular fibres themselves become swollen and softened by the imbibition of the gastric fluid, and are finally disintegrated and liquefied. In the small intestines the pancreatic and intestinal juices convert the starchy ingredients into sugar, and break up the fatty matters into a fine emulsion, by which they are converted into chyle. Although the separate actions of these digestive fluids commence, however, at different points of the alimentary canal, they afterwards go on simultaneously in the small intestines. *Throughout the small intestines the secretions are intended exclusively or mainly to act upon the food, to liquefy or disintegrate and to prepare it for absorption.* But below the situation of the ileo-cæcal valve and throughout the large intestines the contents of the alimentary canal exhibit a different appearance, and are distinct in their color, odor, and consistency. This portion of the contents, or *feces*, is not composed for the most part of undigested remains of the food, but consists principally of animal substances *excreted by the mucous membrane of the large intes-*

tines." Says Dr. Flint, "It is now almost universally admitted that *the digestion of all classes of alimentary substances is completed either in the stomach or the small intestines.*" Magendie emphatically declares, "*I conceive that digestion is completed effectually without the large intestines taking any part in it.*" Professor Martyn Payne, in his voluminous "Institutes of Medicine," ascribes to the gastric juice "the principal agency in the assimilative process," and imputes to the saliva, bile, and pancreatic juice, auxiliary powers of a "problematical" character.

Digestion consists in the conversion of food, first into chyme, and next into chyle; that accomplished, digestion is "effectually completed." Chyme is produced in the stomach by the gastric juice; chyle is formed in the small intestines by the operation of the pancreatic fluid, bile, and intestinal juices. And Dunglison declares that "when the food has attained the lower part of the ileum the process of chylification is accomplished."

In proof of my last point,—that, perhaps, of chief interest and importance in this discussion,—the evidence is drawn both from the anatomical structure of the large intestines, and from the known facts which have been developed by physiologists as to their real functions. In the mucous membrane of the stomach are myriads of follicles, which secrete the most potent of the digestive fluids,—the gastric juice. In the small intestines are the pancreatic fluid and bile, the secretions of large glands, whose ducts terminate in the first division of the intestines, and the intestinal juices, which are the products of glands lying in the mucous membrane of the intestines, which decrease in number as the large intestines are approached. But in the large intestines there is nothing of the kind. *From the ileo-cæcal valve to the anus there is not a gland or a membrane that secretes a digestive fluid.* This is the testimony, I believe, of every anatomist who has written upon the subject.

In the stomach and small intestines food is to be digested, and there we find *secretions* or digestive fluids, fitted to disintegrate and liquefy the food, and thus to prepare it for absorption and assimilation; in the large intestines, on the contrary, we do not find *secretions*, but animal substances which are "*excreted by the mucous membrane.*" Nature has provided glands, which *secrete* digestive fluids in and near the portion of the alimentary canal which is above the ileo-cæcal valve, while she has denied them to the portion which is below that valve. Above are *secretions*; below, *excretions*.

Speaking of the large intestine, Magendie says, "It fulfils sufficiently well the office of a *reservoir*, where is deposited for a time the residue of the chemical operations of digestion, to be afterwards expelled."

And Dunglison says, "The large intestine acts as a reservoir and *excretory canal for the feces.*" Flint characterizes "the process of digestion which takes place in the large intestine as *unimportant*," and declares that "hardly anything but water is absorbed by its lining membrane." And Dalton, as we have seen, forcibly contrasts the appearance of the contents

of the small and large intestines,—their “color, odor, and consistency,” calling the latter “*feces or excrementitious matter*.” Thus we see that the function of the large intestines is neither to commence nor to complete the digestion of food,—the anatomy of the organs forbidding the exercise of any such function, and physiology testifying to the same fact.

Now, I think I may claim to have established irrefutably—1, that the complex process of digestion is an *absolutely necessary preliminary* to assimilation; 2, that this result is reached in the completion of chylification, before the contents of the alimentary canal pass the ileo-cæcal valve; and 3, that the large intestines do not and cannot perform the function of digestion, but that they act as a “reservoir” simply,—an “excretory canal” for the *feces*, whence they are after a time expelled.

Now, if these propositions are true, where is the sense of using so-called “nutritious enemata”? What efficacy can be derived from alimentary substances injected into the large intestines, *unless they can be digested*?

John Hunter called digestion “a species of regeneration.” It certainly is not simply a solvent process. Food is not only liquefied, but it is *vitalized* also. And if alimentary substances are injected into the large intestines, which have no power to *digest* them, they remain inert and dead, as much so as if they were put into a jug.

But, it is asked, may not liquids holding in suspension or solution the ingredients of food be absorbed by the large intestines, and subserve the purpose of nourishing the body? The answer is positive and unequivocal, No; it is only “*by admixture with the gastric juice and the intestinal secretions*,” says Dr. Dalton, that “*liquids holding in suspension the immediate principles of animals and vegetables become modified and rendered fit for assimilation*.” Food injected into the large intestine cannot, therefore, be assimilated, because the *necessary* “admixture with the gastric juice and intestinal secretions” *cannot take place there*.

Nor do the experiments of Dr. W. O. Leube, of Erlangen (*Med. Record*, from *Deutsches Archiv für Klin. Med.*), disprove or militate against the positions of this article, but, on the contrary, they confirm them; for by mixing pancreas with beef to effect *artificial digestion*, he assents to the proposition that *digestion is an essential prerequisite to assimilation*; and his endeavor thus “to transfer to the large intestines a part of the digestive processes which normally take place in the small intestine” is equally a confession “that the large intestines are not digestive organs,” etc. Digestion would be as thoroughly effected by the method of Dr. Leube in a retort as in the large intestines.

The error of supposing that food could be digested in the large intestines, when injected *per anum*, arose, undoubtedly, from confounding the phenomena of *absorption* with those of *digestion*, at a time when the latter were not so well understood as they have since become; and the error has been persisted in from want of due reflection. But absorption is a physical act, purely, whilst digestion is a complex process, both physical and vital.

In the summer or fall of 1856 I wrote a letter to the learned and distinguished Dr. Beuriet-Dowler, then editor of the *New Orleans Medical and Surgical Journal*, intimating a doubt as to the efficacy of nutritious enemata, and requesting him to discuss the question in that journal; I hoped to have the subject illustrated by his great research and enlightened views. In his reply, however, he published several lengthy extracts from European writers to prove that *medicines* injected into the rectum are absorbed, and produce their usual desired effects. Mistaking the object I had in view, and the direction I hoped to give to his investigations, he set about proving what I have never dreamed of questioning, and what every tyro in the profession knows and practises. *But medicines are not acted upon by the digestive fluids as food is*. They do not produce their remedial effects by being digested or assimilated. Whilst *food* must be liquefied and vitalized by admixture with the gastric juice and the intestinal secretions, and thus rendered fit for assimilation, *medicines* are absorbed unchanged, or in new combinations, and circulate in the vessels, until, like all extraneous matter, they are eliminated. *Medicines are not digested*.

Most medicines are poisons, if taken in sufficient quantity; and whether the amount taken into the stomach be less or greater does not affect the question of the influence upon them of the digestive fluids. Now, if a person is known or suspected to have had poison administered to him, either by mistake or designedly, a chemist does not hesitate to determine the question of his having been the victim of a criminal purpose or of an unfortunate blunder. Indeed, he not only determines the fact of poisoning, but he reveals the character of the agent employed. However subtle the instrument of death, or slow and gradual the process of introducing it, the skilful chemist, with his sensitive reagents intelligently manipulated, will disclose the facts of the case. The poison will be discovered in some organ remote from the stomach; perhaps in the very form in which it was swallowed. Although absorbed, it was not digested, and therefore could not be assimilated. Arsenic, strychnia, antimony, opium, etc., etc., have each—to the praise of a noble science, which has thus become the handmaid of justice, be it said—been thus detected.

Food, on the other hand, unlike medicines and poisons, is not only dissolved, but is digested, before it is absorbed. By admixture with the digestive fluids, animal and vegetable substances are reduced to a homogeneous, undistinguishable mass, when all the chemists in the world would find it an impossible task to determine the form or nature of the food which had been thus changed in its physical, chemical, and vital properties.

Some plausibility has been given to the notion that “nutritious enemata” have proved efficacious in sustaining failing strength, by the fact that persons to whom they have been administered, when food could not be received *per vias naturales*, have lived for several weeks. But cases must have occurred in the practice of many physicians where life has been preserved, apparently miraculously,

and no food has been taken in any way. I have in my mind the case of a child, seven or eight years of age, who, in 1870, lived through an attack of typhoid fever which lasted *ten weeks*, who did not allow a *drop of anything* to be received into her body for at least two-thirds of that time. Mr. S. F. Shallcross, President of the Levy Court of New Castle County, Delaware, has communicated to me the fact that his father, who is eighty-three years old, was, in the winter of 1871-72, sick with "*debility*," and that *for sixty-three days, or nine weeks*, during which he nursed his father, *his only nourishment* was "about two tablespoonfuls of brandy, and the same quantity of gum-water, in twenty-four hours." Dr. Burns, of Frankfort, attended the case. Had nutritious enemata been administered in either case, how naturally the remarkable tenacity of life would have been attributed to their nourishing and sustaining powers!

After long and mature reflection upon this subject, I am settled in the conviction that the use of "nutritious enemata," in our day, is one of the many illustrations which could be furnished of the fact that clinical practice does not keep pace with the advances of physiology and other correlative sciences.

NEW CASTLE, DELAWARE, March, 1874.

A SUCCESSFUL CASE OF TRACHEOTOMY FOR CROUP.

Read before the Philadelphia County Medical Society, Dec. 24, 1873.

BY M. O'HARA, M.D.

I WAS called, on Wednesday night, November 19, to see Fannie P., aged 3 years and 8 months, a healthy child suffering with all the symptoms, according to books and teaching, of pseudo-membranous croup. She went to bed well, and arose Monday morning with croup and catarrh; to the latter she had been prone since an attack of measles, a year or so previously. She had never had an attack of croup before, and received home-treatment, in spite of which she steadily grew worse.

There was, at my visit, fever, croupy cough, catarrhal sounds in right bronchus, but no membranous deposit was visible in the throat. The tonsils and arches of the palate were congested and swollen. There was, at times, a spasmodic closure of the laryngeal orifice, but also a gradual and persistent narrowing. The larynx was tender. Her appetite was good, and she took nourishment well. The cough was hoarse, somewhat suppressed. Respiration was audible, and becoming more difficult. I thought surgical aid was required, and stated so to her parents, basing my opinion on the rapidly progressive apnoea and the commencing exhaustion. I had lost a case similar to this, and the temptation was strong to have tracheotomy performed at once. I, nevertheless, wished to try in full all the resources of medical art,—steaming with lime-bath, emetics, hot sponging to the larynx, saturation with alkalies; these relieved somewhat the urgency of the symptoms during Thursday. Thursday night things looked badly, and Friday morning an operation was demanded.

Drs. Carroll, J. H. Grove, and Dr. O'Neill agreed, at 9 P.M., that an immediate operation was necessary to save life; but the parents still refused, and treatment

was continued during the night. Mercurials were given, and the gums touched. At 8 o'clock on Saturday morning, November 22, the operation was skilfully performed by Dr. Grove. Immediate relief followed, the tube was introduced, and respiration was performed naturally. Anæsthesia was effected by chloroform and ether. Their use seemed to me questionable, in the already paralyzed condition of the breathing apparatus. As chloroform, in a recent coroner's jury in Boston, has been denounced, we ought at least to use only ether to be safe from law-suits. There was a moment of syncope, which seemed like death, but the rapidity of Dr. Grove in letting air into the lungs saved life.

The father, constantly present, day and night, to nurse, was taught to remove the tube for cleansing. The inner tube could not be used, as air sufficient could not be carried with it in place. The child was placed in an apartment partitioned off by hanging counterpanes. A saucepan also of slaking lime was kept in the room, and steam from boiling clothes in a wash-boiler, the latter a practical suggestion of Dr. Cohen, worthy of recollection. The patient was kept upon veratrum viride and citrate of potash, with quinine. In consequence of the ten hours' delay from night until morning asked by the parents, the dyspnoea had steadily increased, and at each inspiratory effort there was recession of the base of the thorax, a sulcus around the chest; in fact, just before the operation the recession of the lower part of the sternum and epigastrium might be called almost permanent. There was some hissing laryngeal stridor, and auscultation and percussion showed that collapse of the lower part of the lung had taken place, and this was not observed the night before. There was also scattered lobular condensation or congestion of the lung. Treatment was instituted to prevent pneumonia and bronchitis. The child did well until the night of the 23d, when it showed a feverish oppressed condition, with dyspnoea and exhaustion. The symptoms were alarming, and Dr. Grove was summoned. The tube was at once removed, and found to be sealed with a cement-like substance almost completely. This was removed and the tube replaced, when respiration went on naturally, and the symptoms were relieved. Care was taken to cleanse the tube thoroughly by passing through it a piece of tape.

Dr. Pancoast uses no canula in his cases, but makes an opening by excision, which he keeps free with a piece of lead wire. If it were possible to do this in all cases it would be safer. The tube demands great attention, and in this case required to be retained a month.

The wound kept healthy, sweet oil being the only dressing. No gauze was used over the orifice, but the use of vapor was continued the whole time. No false membrane could be detected. Only liquid food was allowed, and hot poultices were kept constantly applied to the chest.

November 24.—Chest-symptoms are better. Poultices continued. Diaphoretics and quinine are now given. No air as yet passing through the larynx.

November 25.—Up to this time the larynx has been completely occluded, but to-night some air comes through, accompanied by the old croupy sound. The patient took bread to-day: the crumbs, however, produced irritation and choking, which was relieved by a drink of water. The discharge through the tube is less, thinner, and can pass through by the ordinary expiratory effort, though at times it accumulates below the tube and must be removed. Crepitation and bronchial râles still give evidence of some lung-trouble.

November 29.—The seventh day after the operation; the patient weak, and has no appetite. Suspended quinia and fever-mixture, and ordered vegetable tonics and wine whey. The wound is very contractile; tube

has to be replaced rapidly. There is always an increasing vent in the larynx from cough when she drinks fluids. Removed the canula, and replaced it with a larger double tube.

November 30.—Laryngoscope shows the absence of swelling and membrane.

December 1.—Some fever; erythematous redness of one cheek, bronchial râles and congestion of the lower part of the left lung. Ordered magnesia; resumed poultices and diaphoretics.

December 2.—Patient is better; takes eggs, milk, corn starch, oyster soup, etc. Ordered castor oil. On this, the twelfth day after the operation, by closing the orifice, she can articulate for the first time, but the exertion soon fatigues her. Takes two ounces of wine daily. Suspended veratrum viride and diaphoretics; continued tonics.

December 3.—Catarrhal symptoms increased. Had a poor night. Considerable vent in the larynx. Articulates, but with greater croupy sound than yesterday. Much thick muco-purulent matter collects below the tube. From this time the patient did well. On December 16, the twenty-fourth day after the operation, she was practically well. Examination with the laryngoscope showed, as always before, no sign of membrane.

Remarks.—I have called this pseudo-membranous croup, not because we saw no membrane, but because all authorities, by their detail of symptoms, would force us to class it under that head. I have consulted Meigs and Pepper, Reynolds, Aitken, Wood, etc.: they are very diffuse on the subject, but confused. Most of them, as Aitken, define it as a specific disease with exudation on mucous membranes, indicated by alteration of respiration, cough, hoarseness, and laryngeal spasm, to terminate in suffocation or exhaustion. He recommends tracheotomy early, if respiration is so impeded that the demand for oxygen is only satisfied by difficult and forced respiration, or if the patient is becoming exhausted, and not to wait for asphyxiation. He speaks of an insidious form, coming on more slowly, with weariness, weakness, and restlessness, anxious startings out of short slumbers, loss of consciousness, pallor of face, approaching to œdema; in this kind of croup, delay must especially be avoided. The case just narrated had this train of symptoms. Meigs makes three kinds of laryngitis: catarrhal without glottic spasms, spasmodic simple laryngitis, and pseudo-membranous, including in this diphtheria. He makes a grave form of the simple laryngitis, which ensues in death. He is not very clear in distinguishing this from pseudo-membranous, nor, in fact, can it be distinguished. The only certain sign is the presence of false membrane. In the case just narrated there was no membrane seen; yet authors tell us that this is no proof that it is a case of simple inflammation. Meigs and Pepper say that in membranous croup there is a slow, steady, unrelenting progress of the symptoms. This was the case in this patient, together with altered and suppressed voice, dyspnoea, and stridor. She had mainly a continuous increasing obstruction to the entrance of air in the larynx, the cause of which remained until the thirteenth day after the operation, during which time it seemed to be, at least for a few days, completely closed. Again, Flint and Jacoby give, as a test, that in membranous croup

dyspnoea exists both in inspiration and in expiration; in catarrhal croup it is chiefly in inspiration. This case also bears this test, and we are constrained to call it pseudo-membranous, although the existence of membrane was extremely doubtful. In the typical case of recovery under Prof. Meigs's care there was abundance of membrane visible, and recovery complete on the ninth day. Recession of the sternum and epigastrium during inspiration and a deep sulcus around the base of the chest are given by the books as a mark of pseudo-membranous croup. I think this should be laid down as an indication for tracheotomy, but as no evidence of membranous deposit. Any kind of obstruction of the larynx will produce this from atmospheric pressure on the outside of the chest, the counterbalancing pressure within being removed. Auscultation is not to be relied upon, though it was of great service in this case. Too many mistakes have been made by experienced auscultators, where pseudo-membranous croup was diagnosed, while post-mortem examination showed nothing to account for death. Hartshorne, in his "Essentials of Practice," is clearer than others, in stating that the pathological elements of croup are spasm, congestion, or hyperæmia, and inflammation, either ordinary or diphtheritic. A purely inflammatory case without spasm is very rare. Pseudo-membranous does not differ from inflammatory, of which it is only a grade or termination. *Tracheotomy*, of itself, is attended with very little danger, and should be performed oftener and earlier. There is too much prejudice against it at present. When death occurs it is from tissue-alterations, blood-poisoning, etc., and not from the operation. In this case, ten hours' delay, although it was the fifth day, gave us some bad symptoms to contend with after the operation. Many cases of ill success are due to neglect in after-treatment, such as neglect of the tube, blood-poisoning, disease of lung induced by delay. Such cases should be eliminated from statistics, or the statistics thrown to one side altogether. I think the physician criminally negligent who fails to perform the operation if it is in his power. The saving of this child's life brings to me self-satisfaction, though the practical part of the work was performed by Dr. Grove, to whose unremitting kindness, solicitude, and skill I owe so much, and to whom here publicly I wish to render thanks. I also feel indebted to the kindness of Dr. Cohen, who on several occasions endeavored to determine whether this was a case of false-membrane croup or true-membrane croup, or whether it was simply, as Reynolds describes, a case of croup.

BELLADONNA IN INTESTINAL INVAGINATION AND HERNIA.—M. Gallicie (*La France Médicale*), in a paper on belladonna, says it is the special medicament for intestinal invagination, strangulated or not, as also for strangulated hernia. It acts on both the spasmodic and inflammatory elements. In both cases, however applied, its first effect is to alléviate the intensity of pain and to diminish and arrest the vomiting.

NOTES OF HOSPITAL PRACTICE.

BELLEVUE HOSPITAL, NEW YORK.

CLINIC OF PROF. L. A. SAYRE.

FRACTURE OF CLAVICLE.

FRACTURE of clavicle, which this man has, is one of our most common fractures, yet is most difficult of treatment, as is indicated by the endless variety of apparatus suggested for its adjustment and retention. Dr. Paul Eve, of Nashville, Tennessee, has even resorted to cutting down on the fractured ends and wiring them together. In fractures we have one general law of treatment: extension and counter-extension in the proper direction until accurate adjustment, then retention. In these cases, for several years I have used, with marked success, two strips of strong adhesive plaster (Maw's moleskin), without any axillary pads, three or four inches wide, one long enough to surround the arm and go completely around the body, the other to reach from the sound shoulder around the elbow of the fractured side and back, to the place of starting. The first piece is passed around the body below the axillary margin, and is pinned in the form of a loop sufficiently large to prevent strangulation, leaving a portion on the back of the arm encased by plaster. The arm is then drawn *downward* and backward until the clavicular portion of the pectoralis major muscle is put sufficiently on the stretch to overcome the sterno-cleido-mastoid, and thus pull the inner portion of the clavicle down to its level. The plaster is then carried smoothly and completely around the body and pinned to itself on the back, to prevent slipping. This first strip fulfils a double purpose. First, by putting the clavicular portion of the pectoralis major on the stretch, it prevents the clavicle from riding upward; and, second, by acting as a fulcrum at the centre of the arm when the elbow is pressed downward, forward, and inward, it forces the other extremity of the humerus, and with it the shoulder, upward, outward, and backward. It is kept in this position by the second strip, applied as follows: commencing on the point of the shoulder of the sound side, drawing it smoothly diagonally across the back to the elbow of the fractured side, where a slit is made in its middle to receive the olecranon; a soft piece of muslin over the joint of the elbow is of advantage. Before applying the strip my assistant presses the elbow well *forward* and inward, and retains it there while the plaster is continued over the elbow and fore-arm, pressing the latter close to the chest and securing the hand near the opposite nipple, crossing the shoulder at the place of beginning, and there securing by pins. My patient can be well shaken and no displacement occur. If any slack occur it should be taken up at once. I dressed a lawyer in this way who fell near my office at 9 A.M., and he was pleading his case in open court at 11 o'clock. Bandages do not stick, but slip around the body and give no firm support. Never warm the plaster. Sternal dislocations of this bone are also to be treated in this way, with the addition of a third piece of plaster, and a pad over the point of displacement. The strip passes diagonally across the shoulder and body, and its ends are secured to the first piece, or both.

HIP-DISEASE.

Case I.—Girl, 12 years old; hip-disease, with open sinuses; marked deformity; too feeble to walk. Born of healthy parents, and one of a large family of stout children. Fell from stoop five years ago and injured the left hip; confined for two years in an Institution for the Relief of Cripples, in this city, where only constitutional means are used,—bark and mercury: no attempt

was ever made by extension to relieve her sufferings or deformity; the head and neck of the femur are destroyed and the acetabulum perforated. Authors term this the stage of luxation, but of my forty-seven cases of excision I have yet to find one luxated. The capsular ligament is not ruptured, but is displaced,—the edges of the acetabulum having been absorbed by the constant pressure of the end of the femur, which is within the capsular ligament and enlarged acetabulum.

My plan of excising the hip-joint is as follows. Take a short, strong knife, send it home to the bone at a point midway between the anterior superior spinous process of the ilium and the top of the trochanter major; carry the knife downwards in a slight curve until you reach a point opposite the trochanter minor, not passing over the centre of the trochanter, but half-way between its centre and outer border,—the incision should be six or eight inches long; boldly divide all tissues and the periosteum, and do not dissect as for hernia. Opposite the trochanter minor divide with a probe-pointed bistoury the periosteum as far around the bone as possible, at right angles to the first incision, and at its lower limit; a knife is used to cut the rotators attached in the digital fossa;—peel off all the periosteum carefully and effectually, from the diseased bone; by adducting the limb slightly, the bone is denuded of periosteum down to the trochanter, where a chain or metacarpal saw divides the shaft; several sections are often needed to reach sound bone; this is done by pushing the ends of the femur through a slit in the periosteum. In this case two sections are made—the last three inches below the trochanter minor,—when we come to good bone; we then gouge out the diseased bone from the acetabulum, wash out the wound, and fill it with balsam of Peru and oakum, thus allowing more space for new bone, the periosteum being left intact. Never leave the trochanter major; it would plug up our drain-pipe from the diseased acetabulum. Free drainage is essential to success; hence use oakum, and by no means lint or cotton. In this case the head and neck are absorbed, and the trochanter major is rounded off by deposits of new bone, thrown out around the specimen removed; almost a perfect involucrum. Efforts at repair have encased the dead bone, and the patient would have died before its removal by nature; ankylosis existed, due to these new formations attached to the ilium. Place the patient in "wire breeches"—a machine consisting of wire frame, which encloses the body from head to feet, fixing immovably the whole lower half of the body. The sound limb is secured to one leg of the machine,—care being used to stiffen the knee, thus fixing the pelvis,—the lame limb is extended as far as the contracted muscles will allow, and is held by two strips of plaster carried from the ankle to the femur, and secured by a roller; the plaster is brought down around the foot-piece, which works on screws, so that the limb is extended gradually; a roller is then passed over the limb and pelvis, around an arm of the instrument, to act as a perineal band, keeping up constant counter-extension. Pad all points of pressure, and have the anus fit well to the crotch of the breeches. Now the patient is ready for fresh air; our best results have been those exposed freely out-doors. To test the necessity for dividing contracted tendons or muscles, put the tissues on the stretch, and make point-pressure with the finger: if reflex spasm occur, cut, for the part is contracted; if no spasm result, do not cut, as the part will stretch, it is only contracted. In using extension it must be from the femur; have the plaster come above the knee. London surgeons magnanimously acknowledged their failures in hip-disease to be due to not having their extension from above the knee, which was also frequently the cause of synovitis of the knee-joint.

Case II.—Boy, 13 years; third stage, hip-disease; excision performed June, 1873. Waxy liver, spleen, and

kidneys, developed during the progress of the disease, with general anasarca and abundant urinary casts, caused us to refuse exsection; but we subsequently operated with the slight hope that there remained enough healthy tissue in his organs to sustain life. The result has been good: the hip is well, and the deformity lessened. A principle has been established by this and other cases: remove the cause of disease consequent upon hip-joint disease or other exhausting trouble, and you have a prospect of good recovery.

Cases III. and IV. illustrate nature's exsections; fearful deformity presented. This young man suffered eleven years with hip-disease; his thigh is scored with sinuses; ankylosis is complete; the whole femur is diseased. I will remove the dead bone at its lower portion,—leaving seven or eight inches' shortening. This serious result could have been avoided by exsection ten years ago. This girl has had twenty sinuses; two are still open, and dead bone can be detected; there is much shortening; the adduction is so great that the inner sinus cannot be well cleaned; ankylosis was feared, but the pain and tenderness to-day, from handling it yesterday, make us safe in concluding that motion, though slight, was made. A long splint from pelvis to foot, with a hinge-joint, and worked by screws attached to a platform on the pelvis, best allowing abduction and rotation of the limb to be made, will overcome this deformity; passive motion will break up the ankylosis. Otto & Reynolds, 64 Chatham Street, are making one. This splint was first used by me, and with perfect success, in 1868, for a like trouble.

Case V.—This young man has taken prizes in skating since I exsected the head and neck of his femur in 1864. (The class unable to tell which limb had been diseased.) The new joint is perfect.

Case VI.—Girl; first stage of hip-disease, advancing into second. Limb slightly abducted; gluteo-femoral crease less marked than its fellow on sound side. Pelvis has assumed an oblique position; natural rotundity of gluteal muscles diminished, knee slightly bent. My rule for the normal standard of position from which comparison is made in forming our diagnosis of this disease is as follows: Place the patient on her back upon a hard surface, limbs parallel to each other, in continuation of long axis of body, spinous processes touching the table, pelvis fixed; draw a line from the sternum over the umbilicus to the pubes; another from one anterior superior process of the ilium to its fellow; the lines will intersect at right angles if the trunk and pelvis bear their normal relations to each other; if no obstruction exist at the joint the leg can be extended perfectly straight, the popliteal space touching the table. The position in which the diseased limb must be held to give comfort to the patient while the sound limb and pelvis are thus fixed, is the deformity indicating the stage of disease. This deformity is due to tension in the joint from effusion and muscular contraction, the result of reflex irritation—or to complete muscular rigidity. Many such cases are treated by mercury, blisters, cod-liver oil to relieve constitutional tendencies; the joint finally abscesses, and dead bone occurs, as seen to-day. In a majority of cases the head and neck of the femur are destroyed; imprisoned dead bone remains to irritate, constantly aggravated by muscular contractions forcing the end of the bone through the diseased acetabulum. All these cases are decidedly benefited by judicious local treatment. Some authors do not support it. Dr. Ashhurst, one of our best critics, says that local treatment is wrong, and expresses the wish that a new Abernethy would arise to revive and recommend general constitutional treatment. I believe and know that the man who can adjust an apparatus to this hip in a way to give perfect comfort to it, and prevent deformity, and permit the child to get out-doors where it can obtain all the reviving and tonic influences of fresh air and sunlight—that man is the true Abernethy.

Such treatment is worth more than all other forms combined; worth all Abernethy's potions and pills put together!

T. S. SUMNER, M.D.

TRANSLATIONS.

USE OF BATHS IN TYPHOID FEVER.—The use of cold applications in typhoid fever may be made by means of affusions or of the cold bath.

The first of these are indicated in adynamic cases, accompanied by profound intellectual torpor, etc. They act by exciting, so to speak, the reflex activity of the respiratory and circulatory centres, and dissipate those conditions which depend more upon faulty innervation than upon elevation of temperature.

The cold bath, on the other hand, is indicated where it is desired to subtract from the economy a certain amount of caloric, the augmentation of which might prove fatal to the patient.

Brand, of Stettin, one of the earliest advocates of cold baths in typhoid fever, recommended their use every three hours, day and night, the patient remaining in the bath, which had a temperature of 68° Fahr., twelve minutes.

According to him, it is not sufficient to lower the already augmented temperature; it should not be allowed to become elevated.

The effect of cold baths on a healthy person is only temporarily to lower the temperature, and that to a limited extent. The spasmodic contraction of the peripheral vessels drives the blood to the deep cavities, where loss of heat by radiation is prevented to a certain degree, while its production is at the same time augmented, as the amount of carbonic acid exhaled testifies. Then the period of reaction quickly dissipates the effect of the cold application.

On the contrary, it is comparatively easy to lower the temperature of a fever-patient, and this is done not by moderating combustion, but by increasing waste, an action diametrically opposed to that of quinine and alcohol remedies, which address themselves to the former purpose.

The two results of the action of fever in the economy—rapid waste of tissue and elevation of temperature—have their dangers, and carry with them indications for treatment. In hectic fevers the danger is from waste of tissue, not undue elevation of temperature; here no one thinks of using baths. On the other hand, in acute pyrexia the danger is less from waste of tissue than simple elevation of temperature. The whole group of ataxic and adynamic phenomena occurring in such cases depends, doubtless, upon the pernicious action of an overheated blood on the nervous centres.

It is in these cases that the most important point to be gained is the rapid cooling of the blood,—an indication which hydrotherapy alone can fulfil.

Without doubt the application of cold awakens the reflex activity of the pulmonary vessels, just as it reanimates the cutaneous functions and dissipates passive congestions.

While Brand accepts no contra-indications to the employment of cold, except intestinal perforation, Wunderlich advises baths, warm at first, the temperature of which is gradually lowered by the admixture of cold water, in cases attacked by profuse diarrhoea, albuminuria, heart-troubles, or in the case of pregnant women.

Wunderlich regards intestinal perforation, hemorrhage, and collapse, as contra-indications; we cannot partake of this view in the latter instance, and believe, on the contrary, that immersion baths as well as cold affusions are the best agents to prevent that tendency

to paralysis of the vasculo-respiratory centres which is the primary cause of collapse.

A case recently occurring in our wards illustrates this point. A young girl, attacked by typhoid fever, was found one morning menaced with collapse. The nose and the extremities were cold; the axillary temperature was 96.8° Fahr.; the pulse was thread-like, almost imperceptible. Half an hour after the administration of the cold bath the patient had warmed up, the pulse and temperature were raised, and all traces of collapse had disappeared.

What are the advantages, then, of this treatment which has gained such general acceptance, and which in Germany is employed almost to the exclusion of every other therapeutic resource?

It may be asserted that the administration of several cold baths in twenty-four hours will often control and cut off a febrile movement which to all appearances is likely to be violent and tedious.

While fulfilling the indication of lowering the temperature, this treatment at the same time affects favorably the entire group of symptoms proper to the typhoid pyrexia. The nervous centres are first influenced, the delirium is dissipated, the intellectual torpor disappears, and even, in some cases, the subtsultus tendinum and other indications of profound nervous perturbation. The action of the respiratory centres is also favorably modified, inspiration is deeper, softer, and stronger, and the bronchia recover their contractility, throwing off the products of secretion which obstruct them. The circulation of the blood is also improved, the skin becomes soft, tympanites diminishes, and the secretions become more normal.

One single objection may be stated in regard to the use of cold baths in typhoid fever,—namely, that internal hemorrhages are favored thereby.

In 257 cases treated by the cold bath, 18 cases of hemorrhage occurred, or 7 to 100; while by the ordinary treatment, hemorrhage occurs only in 3 to 4 cases per 100. Wunderlich, however, is inclined to doubt that the hemorrhage in these eighteen cases was due to the use of cold baths, since it only came on some hours after their use, when the internal congestion no longer existed. Finally, in none of these cases was the hemorrhage serious, and they all resulted favorably. —*Bull. Gén. de Thérap.* (Prof. Béhier). A. V. H.

OPERATION FOR ARTIFICIAL VAGINA.—Prof. Dolbeau relates, in the *Bull. Gén. de Thérapeutique* for February 15, 1874, a case of congenital absence of the vagina occurring in a girl of twelve who came under his care in the Hôtel-Dieu in 1866. Examination showed the external organs apparently normal, the uterus in position, but no connecting canal. As the child had been suffering for some weeks previous from acute abdominal pains occurring at intervals, an operation was decided upon and was successfully carried out, whereby an artificial vagina was created. At the completion of the operation some dark clots were evacuated from a sort of pouch around the neck of the uterus. By the introduction of the fingers every other day, and later by the use of a metallic bougie when it was found there was danger of its becoming sealed, the canal was kept patulous. Subsequently, this was abandoned, menstruation became regularly established, and six years later the girl was married. Dr. Dolbeau some time afterwards delivered her of a seven months' child, born dead, but of quite large size. The delivery was easily accomplished, excepting that a cicatricial ring, which had to be divided, was found in the upper third of the vagina. The woman's health remained good up to the date of the report.

Dr. Dolbeau concludes that the artificial vagina created in the pre-rectal cellular tissue became capable

of assuming the characters of a mucous cylinder, that coitus was easy, that fecundation was the result, and, finally, that accouchement presented no serious difficulties. A. V. H.

CURATIVE EFFECT OF ERYSIPELAS UPON SYPHILIS.—M. Mauriac believes that, under certain circumstances, erysipelas may exercise a more or less curative effect upon certain of the lesions of syphilis. In support of this view he brings forward two cases, in the first of which the patient, when first brought under his notice, presented mucous patches upon the tonsils, palate, lips, etc.

After undergoing cauterization of these patches, the patient was attacked by erysipelas, which invaded the entire face. Within five days the syphilitic lesions had entirely disappeared.

In a second case, which presented not only mucous patches in the mouth, but also an ecthymatous eruption on the body, an attack of erysipelas of the scalp caused the disappearance of all syphilitic symptoms.

M. Mauriac does not, however, contend that this effect of erysipelas is more than temporary, and he adds in conclusion that the development of this disease is not always a favorable omen for the cure or amelioration of cutaneous syphilitic manifestations. It may, on the contrary, become an aggravating circumstance, when the disease takes a malignant form or has arrived at a cachectic stage.—*L'Union Méd.*, No. 14, 1874. A. V. H.

INFLUENCE OF CEREBRAL LESIONS ON THE LUNGS.—*L'Union Médicale*, No. 14, 1874, contains an abstract of a paper by M. Aug. Ollivier on the production of hemorrhages and other affections of the lungs consequent on cerebral lesions. His observations showed congestion more or less intense, with occasional sanguineous effusion into the pleura and apoplectic centres, either scattered through the entire lung or showing themselves at various points.

These alterations were observed to occur in the lung corresponding to the hemiplegic side, and occurred more frequently following a cerebral lesion located at the base of the brain or influencing it, whether this lesion were hemorrhage, tumor, or softening.

M. Ollivier is disposed to attribute the cause of these lesions to a vaso-motor paralysis, and classes them with the vascularity of the skin and elevated temperature on the affected side which are observed in similar cases. A. V. H.

HYDRATE OF CHLORAL AND MORPHIA IN ECLAMPSIA.—Dr. Condereau, in a letter recently published in the *Bull. Gén. de Thérapeutique*, relates two cases occurring under his observation in which the combination of these remedies was found very satisfactory.

The first was that of a woman 23 years of age, attacked at the end of her first pregnancy by convulsions. Hydrate of chloral alone in the dose of one drachm had proved of no avail, when the addition of a hypodermic injection of three-fourths of a grain of muriate of morphia, succeeded in a few minutes by thirty grains more of the chloral, was followed by almost immediate relaxation without return of the convulsions.

The second case was that of a man 24 years of age, who had been subject to occasional but severe epileptic attacks, accompanied by furious mania, sometimes lasting for days. The hydrate of chloral had been used in this case, also alone, but was not found effectual until combined with a hypodermic injection of the muriate of morphia. The dose of the latter was, as in the other case, three-fourths of a grain, followed in a few moments by a drachm and a half of chloral hydrate. The result was very satisfactory, the convulsions being almost entirely controlled. A. V. H.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 11, 1874.

EDITORIAL.

WANTED—AID BY A DISTRESSED COMMUNITY.

WE are thorough believers in the power of women: in their weakness, or rather by their weakness, they move the world for good or for evil as the case may be. The life-long training of the housewife of course fits her to see at once in public institutions faults as to cleanliness, cooking, waste, etc., which are only detected with difficulty by the average man, or more often altogether escape his inspection. Far more important attributes in fitting ladies for the work of supervising hospitals are a peculiar moral fitness, and in most cases an endless supply of leisure. The possession of the latter is of itself a necessity for success to the would-be reformer; and how seldom can men of prominence in this country boast that they are rich in this needed commodity! With a naturally quick sympathy which when fairly aroused dominates everything,—with a power of self-sacrifice that is very rarely possessed by the sterner sex,—with a gentle persistency which no rebuff daunts and which no obstacles can successfully resist,—no wonder woman often is to the poor wretches in the hospitals and almshouses as an angel from heaven, acting in a quieter sphere the rôle of a Florence Nightingale, and exercising, perhaps in an almost equal degree, those qualities which have filled the world with her renown. There is one institution in this city which we believe to be beyond the power of man to improve,—an institution which,

while it might be deemed a wonder of charity in Dahomey, is in a Christian community a standing disgrace. The readers of our columns need scarcely be told that we refer to the Philadelphia Hospital. The only hope of reform seems to us to lie in a visiting committee of ladies who are socially of such standing as to give weight to their words,—morally of such calibre that they will not flee from appalling scenes of suffering or of neglect, but be nerved by them to persistent efforts,—physically of sufficient presence to withstand the bodily labor and the tax that sympathy lays. Under the periodic visitation of such a committee we believe very much would be accomplished in a very short time. Why some of the active spirits so prominent upon anti-vivisection and other committees for the protection of the “higher animals” cannot stoop to aid the poor unfortunates of their own kind, we cannot tell. We can only pray that a morsel of the energy and effort put forth may fall to Lazarus. We have thought that Bellevue Hospital, New York, alongside of our Philadelphia Hospital, is a monument of mercy, a paradise among hospitals: yet the visiting committee there is doing wonders, if we may believe a writer who seems to know what he is speaking about. He says (*N. Y. Tribune*, March 26),—

“First, then, be it said, that Bellevue Hospital, though without soap during two weeks in January; though at times three patients have slept on two beds, five patients on three beds, and many have slept on the floor without blankets and pillows; though in the lying-in wards during January there were no towels, and not a sufficient supply of clothing to keep babies and mothers clean,—though all these things have been, Bellevue Hospital is in a more seemly condition than ever before, and, thanks to the Training School for Nurses, takes better care of its sick. So radically has it been reformed that, in spite of official opposition, it promises to be reformed altogether.”

Why cannot official opposition and official inertia be met here by a visiting committee?

THE touching solicitude shown by the members of our Obstetrical Society to educate New York up to its own high standard is something truly remarkable; especially since it is not generally supposed that New York needs such instruction. Unless we are wrongly informed, some very good works on that branch of medical science have from time to time appeared from the pens of New York physicians, and it would seem difficult even by flooding them with the Society's papers to make

them acknowledge their own inferiority. Can it be that the learned Society, when by its researches it has brought forth some new and valuable matter, fears to impart it to its neighbors, "lest they become as gods" also, and chooses rather to lose its work in the busy whirl of the Western metropolis, as he who, made wretched by the possession of unwanted riches, sinks them in the ocean to relieve his mind of care?

It seems strange that while we have a journal acknowledged to be fully alive, and representing as none other does the talent and worth of our schools, its pages should not be allowed to present any record of the meetings and transactions, the papers and debates, of one of our principal societies. Is the learned body bound hand and foot by the Manhattan Delilah?

"Down the river did glide, with wind and with tide,
A pig with vast sobriety;
And the devil looked wise as he saw how the while
It cut its own throat. 'There,' quoth he with a smile,
'Goes Philadelphia's Obstetric Society.'"

SOME weeks since, in a book-notice, we took occasion to anathematize the American habit of pirating English books. This has given origin to the letter printed below. We did not say that the book was pirated, but only stated that it had the appearance of having been so. We are very glad to see that constant dropping has worn away stone; that under the steady fire of the medical press the publishers are beginning to acknowledge that even authors have rights; and we sincerely trust that the habit of stealing other men's property will soon be a thing purely of the past.

11 NEW BURLINGTON STREET, LONDON, W. }
17th March, 1874. }

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—We are glad to be able to inform you that the American reprint of "Lectures on the Clinical Uses of Electricity," by J. Russell Reynolds, reviewed in your number of 28th of February, is not, as you fear, a pirated edition, but has been published by Messrs. Lindsay & Blakiston under an arrangement satisfactory both to the author and to

Your obedient servants,

J. & A. CHURCHILL,

Publishers in England of the said work.

WE see by the Annual Report of the Episcopal Hospital that a contract was entered into last summer for the erection of the east wing of the building at a cost of \$111,500, and that the foundation-walls of the building are all finished. Of the required amount \$61,000 have been already

subscribed, leaving \$80,000 still to be raised for the completion and furnishing of the wing. Situated in a distant and formerly neglected part of the city, among a population probably needing hospital accommodation more than any other of our city, this institution has done an excellent work, and we trust that it will be liberally furnished with all that it needs to enter upon a career of increased usefulness.

THE old civilization of the British Islands does not seem to differ very much from the newer civilization of this country, in that it considers killing no murder, provided it be done by quacks. Thus, we learn from the London *Lancet* of March 14 that a roadside "professor" who killed a young man by giving a fatal dose of arsenic for a cough was, after conviction, sentenced "to three months' imprisonment, without hard labor." The extenuating circumstance in the case, which produced this trifling sentence, was, that the professor did not know arsenic was so poisonous.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held December 24, 1873, at 8 o'clock P.M.

Dr. EDWARD WALLACE was called to the chair.

Dr. M. O'HARA read the report of a case of successful tracheotomy. (See current number of the *Times*.)

Dr. J. S. COHEN stated that he had seen the case of Dr. O'Hara several times since the operation, and was in some doubt as to whether it were not a case of acute laryngitis of children, with submucous organizable effusion, resting this opinion on the absence of any evidence of membrane, the tenderness externally, the immediate recuperation after the operation, the impossibility of respiration without the tube for so long a time, and the swollen condition of the upper portion of the larynx which had prevented laryngoscopic inspection of the interior. He had no doubt as to the propriety of the operation, and believed that cases of simple inflammatory laryngitis were not relieved from suffocation by tracheotomy, because they were mistaken for croup, which many think impossible to overcome by the operation. Persons who have been unfortunate in their first few tracheotomies for croup were too apt to abandon the operation, yet several prominent tracheotomists had lost numbers of cases before they had succeeded in saving one, but still they persisted; and, as the result of several hundred operations, their success had reached the average proportion. He had referred to the retention of the tube. In some undoubted cases of croup there had been, for various reasons, an impossibility to breathe without the tube, though in most instances it could be removed from the fifth to the ninth day, and, exceptionally, much earlier.

The operation should be performed early, before the blood was poisoned by the retained carbonic acid; but cases had been saved at the last extremity. Continuous and increasing dyspnoea with sub-thoracic inspiratory sinking-in, would, he believed, indicate the time for operation, provided these symptoms had existed two or three hours, or even only an hour, and remained insusceptible to the ordinary modes of relief. When the propriety of the operation suggested itself for the first time, there was little time to lose; too long a delay might compromise the result. He believed a great deal of success depended on the after-treatment. The patient, his disease, and for the first day or two his tube, particularly, needed attention. He believed that the surgeon, or a competent and responsible medical representative, should stay by the patient the first night after the operation; and, in some cases, the second night also. Cases are sometimes lost by allowing the tube to become stopped up, and the patient dies in the very condition for the relief of which the operation was instituted. He was not prepared to assert that these patients would have lived if the after-attention had been everything that could be desired; but he did believe that they did not obtain a fair chance for their lives. With regard to the statistics on the subject, it was hard to get much satisfaction from them, except that cases were saved; and Dr. Cohen said that he was of the opinion of those who were satisfied with this fact, without inquiring as to the proportionate number saved. The published statistics of the Parisian hospitals, and of many private operators who had reported their unsuccessful as well as their successful cases,—now amounting to thousands,—show a proportionate saving of one in from three to four cases. Individual records must be taken at their individual worth. He believed with Trousseau that, with proper care and attention, at least one-half of the cases suitable for operation ought to be saved in private practice.

Dr. H. LENOX HODGE said that he was much interested in the subject which Dr. O'Hara had brought before the Society in his carefully-prepared paper full of pointed thought in regard to his case and the operation.

Dr. O'HARA asked the question whether an anæsthetic should be used.

Dr. HODGE remarked that while he employs anæsthetics in almost every other operation in surgery, he does not use them in tracheotomy. When the trachea is first opened, there is, for a few moments, almost a cessation of respiration; and not unfrequently artificial respiration has to be resorted to. For this reason the child should be in the best possible condition to respond to the surgeon's efforts, and not unconscious from an anæsthetic. The child does not suffer much pain, as the impeded respiration has long since lessened his sensibilities. Dr. Hodge recommends that a portion of two or three rings of the trachea be excised, as has been done in this city for a number of years by Professor Pancoast. In addition to this, Dr. H. employs the tracheal tube for a few days. When such a section of the trachea has been made, the tube is easily inserted without a director, may be removed without any danger of impairing respiration, and can easily be replaced. Dr. H. referred to one case of membranous croup, in which the child would have died if it had not been for this section. In a paroxysm of cough and apnoea, with the tube in place, death was imminent; the tube was withdrawn, and a mass of membranes discharged through the section which could scarcely be forced afterwards through the tube. Some have objected to the section of a segment of the trachea, that in after-years the scar, by contracting, would interfere with the respiration and the voice. Experience has shown that this does not result in the least degree. By the operation many lives may be saved which otherwise would

be lost; and even when life is not saved, relief is given to the terrible dyspnoea.

Dr. HODGE reported four cases of tracheotomy on account of membranous croup; and of these four, three lives were saved. He would recommend that the trachea be opened just beneath the isthmus of the thyroid gland, as high as possible without injury to the gland blood-vessels; that a segment of the trachea be excised, and that the patient be kept for a long time in a moist atmosphere at a temperature of 80° Fahr.

Dr. P. D. KEYSER asked what kind of canula the gentleman used. He had seen a flexible tube used in Berlin and Paris which did not produce friction and irritation in the trachea. Cases have died after the operation, from tracheitis, produced by the use of an inflexible instrument.

Dr. HODGE, in reply to Dr. Keyser, said that cases had been reported in which the tracheal tube had produced ulceration even into the innominate artery. One advantage of the operation as above recommended was, that the tube could soon be dispensed with.

REVIEWS AND BOOK NOTICES.

THE PUERPERAL DISEASES. Clinical Lectures delivered at Bellevue Hospital. By FORDYCE BARKER, M.D. New York, D. Appleton & Co., 1874.

We confess to a weakness for a good clinical lecture, whether delivered to the listeners of the amphitheatre or through the press to the listening world. Since we read, with a rapture that time has somewhat toned, the "Lectures on the Renewal of Life," no book of the kind has pleased us more than "The Puerperal Diseases." The happy union of the clinical and didactic, the extreme fitness of the well-selected cases to the remarks, and of the remarks to the cases, the excellent note-taking in the cases, and the author's clear statement of his own opinions,—a clearness not at all dogmatic,—give a life and reality to the work which impress us with confidence in its truth.

The scope of the work is not too wide, not too limited; everything is not crowded upon us in clinical form, like a polypharmic pill which hopes to pass unnoticed by its silver coating. The diseases treated are all well bound together by a strong natural union,—the puerperal state; all bring us in their study to the bedside of the newly-delivered woman,—nowhere else. They can, from their limited number, be remembered as a whole in their various relations and connections. The book has a being and an entity: like a poem, it evidently grew, was not made.

The author claims that this is the only work of the kind in the English language: it is the digest of nearly twenty years of clinical teaching in Bellevue Hospital, made up from phonographic reports, condensed and brought up to the standard of the times.

Lecture I. treats of puerperal convalescence, and contains many practical suggestions. The author, however, recommends placing the patient upon the hands and knees where the bladder cannot be emptied in the recumbent position after labor, which we hardly think entirely sound advice. To say nothing of the danger from hemorrhage, the risk of the entrance of air into the vagina and uterus has been lately pointed out as being much greater in this position than in any other. Generally, we think, the secret lies in an early attempt, and in never allowing the patient to entertain the idea of there being any difficulty in the recumbent position, and enjoining upon the nurse to make moderate pressure over the pubis during the

effort. Should this fail, we think the catheter preferable to the posture mentioned above.

In retention from over-distention, the author uses ergot in fifteen-drop doses, often repeated; but many of these cases have already taken ergot in much larger doses shortly before, and in fact it has been claimed that ergot favors retention.

On page 8 the author speaks—in treating of after-pains—of “certain rare cases purely neuralgic,” where the uterus is small, firm, but exquisitely sensitive to pressure; cases which do not yield to opiates, but are successfully treated by full doses of quinia and chloroform liniment applied externally. This suggestion we consider of great value. He also employs vaginal injections of dilute carbohc acid in all his private puerperal patients for the first few days: why not also in his hospital practice we fail to understand, where, if ever, their use seems specially indicated.

Where purulent leucorrhœa succeeds the cessation of the lochia we are advised to make immediate examination with the speculum, the author expecting in such cases to discover erosion of the cervix, and by treatment greatly to hasten convalescence.

For delayed involution he recommends ergot, nux vomica, and tinct. ferri chl., using the tincture of nux vomica in the somewhat large dose of fifteen minims or about thirty drops, which seems to us liable to affect the nursing infant when repeated several times a day.

On page 18, treating of secondary hemorrhage, after injecting dilute persulphate of iron, of the use of which he is a strong advocate, he says, “If your patient shows no signs of shock from loss of blood, give thirty drops of Squibb’s fluid extract of ergot with twenty drops of the tincture of nux vomica;” and a little farther on, “If the patient exhibit shock from loss of blood, do not give ergot till the reaction is established.” In these sentences the author gives either very valuable or very dangerous advice, and the question hinges upon the fact whether we have any proof that ergot increases shock, for we have proof that it is very efficient in preventing hemorrhage, and unless there be certainly danger from its administration under the circumstances its delay is dangerous. The question in our present state of knowledge is a difficult one. If ergot, as many believe, causes contraction of the vessels of the spinal cord, and if the resulting anæmia of the cord tends to deepen or prolong the condition known as shock, then its administration may do more harm than the good to be expected from its action on the uterine fibres.

While he warns against leaving fragments of placenta and membranes in the uterus, we do not see that the author has anywhere laid stress upon the necessity of a careful examination of the removed secundines, which so often would tell their own story.

Where portions of placenta have been unavoidably retained, and hemorrhage results, the advice given is, if the os be firm and contracted, to tampon the cervix with sponge-tent, and apply a pad and binder firmly over the uterus, though it is admitted that patients have died of accumulation of blood in its cavity “two, three, and four weeks after parturition.” After dilatation by the tent, in six or eight hours he attempts removal of the offending body, and, if successful, injects the cavity with persulphate in dilute solution. Where the os is flaccid, the injection alone is recommended, and in either case he administers a rectal enema of an ounce of turpentine with half an ounce of olive oil. In this connection ergot is not noticed, though we cannot but think its administration would be as useful as the pad and binder.

Lecture II. is upon the diet of puerperal women. The author is an enemy of restricted diet. No parturient Oliver would need to ask him for more. He administers beef-tea early, and full diet as soon as appetite

demand it. He finds nurses unwilling at first, but growing rapidly enthusiastic; which we take it is one of the main dangers of the liberal system, and confess we are still in favor of moderate restriction for the first few days.

On page 29 we find some valuable hints about the use of purgatives. The tendency of castor oil to bring down and aggravate hemorrhoids is noticed. Where these exist, the author recommends either an aloetic pill or a liquid preparation of senna, jalap, and nux vomica. For the cure of painful piles the author relies upon small doses of aloes, combating the idea that they aggravate this condition in puerperal women. Forcible dilatation of the sphincter ani—after the method of Van Buren—he considers the best procedure where they are developed during labor, selecting the moment after the birth of the child and before removal of the placenta.

Lecture III. treats of laceration of the perineum. In regard to support of this structure, the view of the author (p. 46) is, “that he is confident that a majority of lacerations under his own notice have occurred from the patients suddenly withdrawing themselves from the supporting hand,” evidently favoring support; while, however, he subsequently states that the term “support” is an unfortunate one, and closes the chapter by quoting largely from the paper of Dr. William Goodell on this subject.

Lecture IV. treats of thrombus of the vulva and vagina; Lecture V. of puerperal albuminuria. This chapter and the two following on puerperal convulsions are illustrated by remarkably striking and pertinent cases. The author’s experience has been extended, and his opinions are decided. He considers that the albuminuria discovered after convulsions have occurred is more often the effect than the cause of the convulsions, yet does not deny the danger of pre-existing albuminuria, as on page 114, when speaking of its treatment, he says, “I can truly affirm that I now rarely encounter puerperal convulsions when the previous detection of albuminuria has led me to be particularly apprehensive of their occurrence. Indeed, I will go further, and say that in most cases where any of the predisposing causes that I have mentioned are discovered sufficiently early, they may be successfully treated, and convulsions will occur only in a small percentage.”

The view of the author seems to be that both convulsions and pre-existing albuminuria are manifestations of some existing morbid cause, probably (page 110) “the highly congested state of the venous system.” On page 112 he gives the following as the predisposing causes of convulsions: “albuminuria, hydræmia, anæmia, uræmia, and primiparity,” and adds “hereditary and atmospheric influence.”

In the treatment of convulsions occurring before labor, bleeding is recommended if the pulse be full and hard, and evidences of cerebral congestion apparent: he then gives a brisk purgative, preferring elaterium if the patient be comatose, calomel and jalap if not. He avoids stimulating enemata, and endeavors to arrest the convulsions by inhalations of chloroform, suspending it during the attacks, unless the intervals be very short; and, to prevent a return, the hypodermic injection of morphia in full doses. The alleged danger of fatal narcotism from renal lesions he considers more imaginary than real. He considers it—the morphia—the most efficient means yet known for allaying that irritation of the spinal system which culminates in convulsions, and that uræmia does not contra-indicate the use of this agent.”

Chloral hydrate he has not found serviceable. Where “delivery irritates less than delay,” he delivers. After labor, the question of bleeding resolves itself somewhat into how much blood has already been lost: if less

than usual, the author advises bleeding, elaterium, and diuretics. If the patient be anæmic and exhausted, he would use morphia, but no chloroform.

Lecture VIII., on Lactation, we recommend to the reader for its excellent treatment of the management of sore nipples. Recognizing that there are sore nipples, the author endeavors rationally to discriminate in their treatment. One sentence we light on, p. 137, which is worth more than many books: "If the ulcerative process have commenced, stop nursing from that nipple." How much suffering and consequent destruction of health would be avoided were this plain precept always put in practice! The author advises, as a lotion preventive of erosion and excoriation, a ten-grain solution of the nitrate of lead. It has been vaunted as a remedy rather than a preventive, and as a remedy we have met with but indifferent success with it. We would remark that where the solution has failed, cure has followed the use of the powdered nitrate dusted upon the excoriated surface.

The chapter on Mastitis and Mammary Abscess aims also at a clear discrimination of the varieties of the complaint. The author does not consider *belladonna*, however early and freely used, as capable of arresting the formation of pus. He seems a little doubtful even of its power in arresting the secretion of milk.

Puerperal Mania, Relaxation of Pelvic Symphysis, and Phlegmasia Dolens, are the subjects of the three succeeding chapters. The remainder of the book is taken up principally with that group of diseases sometimes included under the general head of puerperal fever, which the author, however, considers a distinct zymotic disease.

On p. 476 he sums up his opinions in a distinct "confession of faith," the points of which briefly are, that it is a fever peculiar to puerperal women,—its symptoms not the consequence of local lesion; it is of the class known as zymotic; we are ignorant of its specific cause, which "may be either epidemic influence, contagion, infection, or probably nosocomial malaria;" that death may occur without any local lesion sufficient to account for it, and that while erysipelas, scarlatina, etc., may develop puerperal erysipelas, puerperal scarlatina, etc., they cannot cause true puerperal fever. In accordance with such views, we find puerperal peritonitis, pyæmia, and septicæmia treated of as distinct affections. Space and time fail to allow us a detailed account of these valuable chapters. The author's argument, to some not convincing, must to all seem able and candid; while the views of others are stated with fairness. He advises strongly the employment of veratrum viride in puerperal fever and peritonitis; and the employment of full doses of quinia in these groups of diseases.

Much has been said of the practical element in the American character, and, while in its medical literature this has been too often another name for shiftlessness and mechanical performances, we are glad to point to the present work as one eminently and truly practical. Clinical lectures most often fail when we attempt to apply their teachings to actual practice. The lines of demarcation, so sharply drawn in the lecture or the book, vanish at the bedside; disease complicates disease, till the student longs in vain to meet one of those typical cases that he knows all about, but which seem to flourish only on paper or in the hospital atmosphere. Few books of the kind will stand this test, but, if we mistake not, this is one of the few.

E. W. W.

A CLINICAL HISTORY OF THE MEDICAL AND SURGICAL DISEASES OF WOMEN. By ROBERT BARNES, M.D. Lond. Philadelphia, H. C. Lea.

The author of "Obstetric Operations" has already

made himself the friend of many a *distract* brother in the profession, and the rare charm of that work is not wanting in the present volume. He aims, not at a mere compilation of the works of others, but to draw largely from his own experience and "to bring into the circle of gynæcological literature new illustrations:" of his success in this endeavor the reader must judge for himself.

The volume before us—the American edition, published by Henry C. Lea—contains nearly eight hundred pages, with one hundred and sixty-nine engravings on wood, very many of them original with the present work. The chapters are full, thorough, and well written; the evident aim throughout the book being the sometimes forgotten one—to teach how to cure or palliate disease. There is no show of erudition, no overwhelming citation of authorities to display the extent of the author's reading, but he leaves it for the reader to judge whether he be familiar with them or not.

The violent rider of no hobbies, its author is a man of decided and original views, which the critic may at times dissent from, but can by no means despise.

An extended review of this book is not our intention, but we may say that a careful perusal has discovered to us but slight grounds for fault-finding; and while comparisons are odious, the reader will not be disappointed even though he take up the book with a very exalted idea of its merits.

GLEANINGS FROM OUR EXCHANGES.

ICHTHYOSIS LINGUÆ (*The Lancet*, March 14, 1874).—At a meeting of the Royal Medical and Chirurgical Society Mr. W. Fairlie Clark read a paper on this disease. According to him, it manifests itself in an overgrowth of the papillary and epithelial elements of the mucous membrane, and it is the dorsum of the tongue which is affected in the majority of instances. In some cases the enlarged papillæ may be seen sprouting up in small groups, in others the whole of the affected surface is smooth, hard, and almost cartilaginous. It presents either a silvery or a snow-white appearance, quite different from any fur which ordinarily covers the tongue. When the disease has once manifested itself, it is very persistent. Though it sometimes responds a little to treatment, and though it varies slightly, it never wholly leaves a spot which it has once attacked.

It may be distinguished both pathologically and clinically from warts, corns, and papillary tumors of the gum, in two ways. 1. It attacks only the tongue and the inside of the mouth; no other mucous membrane is subject to such an affection. 2. It slowly spreads, but gives only slight inconvenience and no pain. In this state it may remain many years, but sooner or later it assumes the characters of epithelial cancer. Its essential nature appears to be that of a chronic inflammation, accompanied by an overgrowth of the papillæ and a loss of power to throw off the effete epithelium. It is much more common in men than in women, and never occurs before puberty. A venereal ulceration may be its starting-point, but there is no reason to think that it is always associated with syphilis. If the disease presents itself in a very early stage, it should be promptly and thoroughly excised. On the other hand, when it has become epitheliomatous, no time should be lost in performing an operation. But during the whole middle period the best thing that can be done for the patient is to study his general health. If any local measures are used, they should be of an unirritating kind. If any jagged teeth are present, they should be removed. At the same time, the patient should be advised to guard his tongue against all

sources of irritation, and to pay particular attention to his digestion. Under this treatment the ichthyotic coating often alters for the better, though it is never altogether removed.

ACUTE PERIOSTITIS OF THE OCCIPUT AND UPPER CERVICAL VERTEBRÆ (*Boston Medical and Surgical Journal*, March 19, 1874).—George Atwood, M.D., reports the case of a stout, healthy man, æt. 50, in whom an erysipelatous inflammation of the face and neck was followed in about a month by severe pain which seemed at first to be neuralgic, but soon developed alarming characters. There were frequently-recurring spasms of the neck; the muscles were rigid; the jaw was tightly closed; the patient could only take liquids, and these, on being swallowed, excited spasms; he could not lie down in bed, for immediately on making the attempt spasmodic action would follow, so as to render the act impossible. On moving the head, pain would commence in the neck, and extend upward over the back of the head, and downward to the shoulders, but never any farther. The pulse was 95, and at times intermitting. During the next four weeks he did not lie in bed, but slept in a chair when he was not walking the room.

He was placed on iodide of potassium, bromides, cod-liver oil, strychnia,—with tincture of iodine, blisters, and counter-irritation to the neck,—and obtained some relief, which was, however, only temporary. A month or two later, he had a paralytic attack, and three months from the commencement of his troubles he expired suddenly.

On dissection, the condyles of the occiput, both articulating surfaces of the atlas, the axis, and the odontoid process were denuded and eroded, the latter feeling smooth and like a piece of ivory. No induration of the tissues, and no effusion of pus or lymph, was apparent; but the periosteum and ligaments around the spine, and on the base of the occiput, to the extent of an inch from the foramen magnum, could be easily torn; the softening being more marked on the left side than upon the right, although the tissues generally were of a dull red color and softened. The transverse ligament connected with the odontoid process was destroyed, and mobility of the head was quite free.

LARGE DOSES OF BROMIDE OF POTASSIUM IN EPILEPSY (*The Lancet*, March 14, 1874).—Dr. Otley reports a case of severe epileptic convulsions occurring in a man aged 21. For two days he was never three hours at a time without a paroxysm, and they increased in frequency and violence until he had five in twenty-five minutes. Respiration was accelerated, and the patient was comatose and almost hemiplegic. He was then ordered twenty grains of bromide of potassium every hour. In half an hour the fits were less frequent, an interval of four hours then occurred without any convulsion, and nine hours after the administration of the first dose he had his final paroxysm. He continued to improve in every particular. On the following day the bromide was decreased to twenty grains every four hours, and then gradually lowered to twenty grains three times a day, which dose he was ordered to continue for a twelve-month.

BROMIDE OF POTASSIUM IN EPILEPSY (*The Dublin Journal of Medical Science*, February, 1874).—At a meeting of the Medical Society of the College of Physicians, Mr. Thomas Hayden read a paper on the use of bromide of potassium in epilepsy, and gave three cases, in all of which a marked amelioration in the condition of the patients had resulted, though it could not be asserted that they were completely cured. He found the full benefit of the salt could be obtained by giving thirty grains thrice daily, and the only symptoms of

bromism caused by this dose were vertigo, indistinct articulation, and an unsteady, tottering gait. He believes the efficacy of the drug to be limited to a reduction in the number of the fits and a mitigation in their severity, while at the same time the nutrition of the nerve-centres is promoted, as judged by the improvement of memory and of self-confidence, and the cessation of muscular tremor on the part of the patient. He could not agree with Dr. Darby, who had tried bromide of ammonium with young females, and had obtained more favorable results than from the use of the potassium salt. He thought, on the contrary, that it was precisely and especially in cases of epilepsy associated with uterine derangements that the bromide of potassium was efficacious and the bromide of ammonium not so. Dr. Fitzpatrick had found the most benefit from its use in the minor form of the disease, in those cases which merely occurred during sleep, or which were dependent on uterine irregularities in the female, or on seminal irritation in the male.

A RAPID CURE FOR TAPE-WORM.—A. J. Schafish, of Washington, says, *inter alia*: I made no preliminary provisions further than to forbid the patient from taking any breakfast the day I intended removing the worm, and giving him a large dose of Rochelle salts the preceding night. At ten o'clock in the morning he had the following at one dose:

R Bark of pomegranate root, $\frac{1}{2}$ ounce;
Pumpkin-seed, $\frac{1}{2}$ drachm;
Ethereal extract of male fern, 1 drachm;
Powdered ergot, $\frac{1}{2}$ drachm;
Powdered gum arabic, 2 drachms;
Croton oil, 2 drops.

The pomegranate-bark and pumpkin-seed were thoroughly bruised, and, with the ergot, boiled in eight ounces of water for fifteen minutes, then strained through a coarse cloth. The croton oil was first well rubbed up with the acacia and extract of male fern, and then formed into an emulsion with the decoction. In each case the worm was expelled alive and entire within two hours. No unpleasant effects followed.

One curious fact that I have noticed is that in each case the worm was passed with the head firmly fastened to the side of its body at about the widest part, from which it was with difficulty removed; also that the worm was twisted and doubled into various knots. In one specimen, only fourteen feet long, I have counted and untied no less than forty-seven of such knots. I have no doubt that, to escape the effects of the medicine, in his distress, he fastens himself to his own body, in this way loosing his hold of the intestines, and is driven forward with the other contents of the bowels.—*The Druggist's Circular*.

REST AS A THERAPEUTIC AGENT (*The Dublin Journal of Medical Science*, February, 1874).—Dr. J. Magee Finney, under the above title, has written an interesting paper detailing a number of cases occurring in his practice, some of which illustrate the importance of physical and physiological rest as a curative means. He alludes to the hygienic and therapeutic importance of the law that, in the recovery from any illness, long or short, exercise, to be beneficial, must be accurately proportioned to the strength of the individual, and must never be carried to the extent of actual fatigue or temporary exhaustion. In cardiac diseases rest is particularly important, and in dilatation, pericardial inflammation, and stenosis or patency of the mitral orifice it is imperatively demanded. In the treatment of internal aneurism, rest affords the best possible means of placing the patient on the way to nature's cure.

FRACTURE OF THE CLAVICLE TREATED BY PLACING THE ARM BEHIND THE BACK (*Edinburgh Medical*

Journal, February, 1874).—M. Broca recently healed a case of fracture of the left clavicle, in which the fracture was near the middle of the bone, and was oblique from above downwards and from without inwards, the fragments riding one another considerably. After numerous plans of treatment had failed to reduce the fragments, he placed the arm in a semi-flexed position behind the back, where it was retained by a bandage for eighteen days, with the effect of completely adjusting the fractured surface, and producing an excellent cure. For a few days longer a sling was used. The patient, a man of considerable nerve, complained of the pain and inconvenience of the method only the first twenty-four hours.

BILLROTH'S OPERATION FOR REMOVAL OF THE WHOLE LARYNX.—The patient was exhibited to the Imperial Medical Society of Vienna. The operation had been performed some time previously, and, thanks to a very ingenious apparatus, the man was enabled to speak and swallow. Many contrivances were tried before the successful one, which consisted principally of two curved canulæ, to which were added a trachea-tube and a voice-canula. The apparatus for phonation was supplied with a peculiar kind of tongue made of very thin silver. The patient was desired to read aloud before the members of the Society, and, though he spoke pretty distinctly, great attention was required to follow him. The poor man looked very thin and anæmic, and it was feared that carcinoma would ere long break out in other parts of his frame. Billroth's operation remains, nevertheless, a great surgical feat.—*London Lancet*.

MISCELLANY.

At a meeting of the board of trustees, April 7, Dr. Wm. H. Pancoast was elected to the position of Professor of Anatomy in the Jefferson Medical College, on the fifteenth ballot.

NEW YORK HOSPITAL.—The Governors of the New York Hospital have purchased the "Thorne" mansion in West Sixteenth Street. The house is about 66 by 80 feet, and three stories in height. In the rear of this the Special Committee recommend the erection of a reception-hospital for acute surgical and medical cases, with a capacity of from 50 to 90 beds. They estimate the cost of the hospital building at \$170,000, of its furniture at \$20,000, and of the engine-house, laundry, and vaults at \$30,000. The probable yearly expenses of the reception-hospital were estimated at about \$40,000. The recommendations of the committee were unanimously adopted by the Board of Governors, and the Thorne property was secured for \$20,000. The first floor of the house will be used for offices; the second for the library and pathological cabinet; the third floor for the hospital staff, and probably some private wards. Possession will probably be obtained about April 1. Additional ground in the vicinity will probably be obtained.—*Tribune*, March 18.

A BIT OF EXPERT-TESTIMONY.—When Orfila, the celebrated French chemist, was on one occasion a witness at a trial for poisoning, he was asked by the president if he could state the quantity of arsenic

requisite to kill a fly. "Certainly, M. le Président," replied the expert; "but I must know beforehand the age of the fly, its sex, its temperament, its condition and habits of body, whether married or single, widow or maiden, widower or bachelor."—*Boston Journal of Chemistry*.

HONORS TO TRAUBE.—On January 25, Prof. Traube ended his twenty-fifth year of service at the Berlin Charité. In consideration of the character of this service, the directors of the hospital gave a celebration dinner, at which most of the professors of the University, and many other physicians, were honored guests.—*Wiener Med. Presse*, February 15, 1874.—*Clinic*.

The English pharmaceutical chemist, Thomas N. R. Morson, died on the 3d of March last, from paralysis, in the seventy-fifth year of his age. He was the first man who manufactured the sulphates of quinia and of morphia in England.

A YORKSHIRE PRESCRIPTION.—

"Too pennorth Oil of Vermins
Wan pennorth Seraph of Eyelets
Wan pennorth Seraph of Squeels."

NOTES AND QUERIES.

DR. HASSALL has recently analyzed nineteen samples of sherry wine,—eight of them of the highest quality procurable in the London market. Not one of them could be considered as a pure and natural product of the grape; all of them had been heavily fortified by the addition of spirit, and seventeen of them contained a notable amount of the sulphate of calcium.

At a stated meeting of the College of Physicians of Philadelphia, held April 1, 1874, Prof. Gross announced the death of Prof. Henry Miller, of Louisville, Ky., and offered the following preamble and resolutions, which were adopted:

"Whereas, The College of Physicians of Philadelphia has heard with profound regret of the death of Prof. Henry Miller, M.D., of Louisville, Kentucky, an Associate of this College; and whereas, it is meet and proper, when a great and a good man dies, that his surviving friends should record their opinion and feelings of his worth; therefore, be it

"Resolved, That in the death of Dr. Henry Miller, for nearly a third of a century Professor of Midwifery, first in the University of Louisville, and afterwards in the Louisville Medical College, medical science has lost one of its most zealous votaries, obstetric medicine one of its most instructive and lucid expounders, and American authorship one of its most able and distinguished writers.

"Resolved, That a minute of these proceedings be recorded upon the books of this College, as a mark of our appreciation of the worth of our deceased associate; that a notice of them be published in the medical journals of this city, and also that the Secretary be instructed to send a copy of them to the family of the late Professor Miller, with the assurance of our heartfelt sympathy in their bereavement."

JOHN H. PACKARD,
Secretary.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 31, 1874, TO APRIL 6, 1874, INCLUSIVE.

PETERS, D. C., SURGEON.—Granted leave of absence for sixty days, on Surgeon's Certificate of Disability, with permission to leave limits of the Division. S. O. 8, Division of the South, March 31, 1874.

HALL, J. D., ASSISTANT-SURGEON.—Granted leave of absence for thirty days, to take effect when a relieving officer shall have reported at Fort Benton. S. O. 56, c. s., Department of Dakota.

SATURDAY, APRIL 18, 1874.

ORIGINAL LECTURES.

REPORT OF TWO CLINICAL LECTURES ON THE RELATION OF RENAL DISEASE AND HEART-DISEASE.

BY JAMES TYSON, M.D.,

One of the Visiting Physicians and Pathologist to the Philadelphia Hospital.

Reported by LOUIS STARR, M.D.

I.—HEART-DISEASE TO KIDNEY-DISEASE.

GENTLEMEN,—I desire to invite your attention, in the course of perhaps two lectures, to the consideration of combined heart- and kidney-disease, a subject which has excited much discussion, and in regard to which, until comparatively recently, no very definite conclusion has been attained. At first it was supposed that the primary lesion in this combined affection was always seated in the heart, but on further investigation certain cases were observed in which disease of the kidneys unquestionably preceded heart-disease. Hence, in the reaction which followed, the kidneys were for some time held to be the invariable starting-point. At present, however, it is generally acknowledged that while most frequently disease of the kidney occasions alterations in the heart, there are undoubtedly many cases in which this order of sequence is reversed.

In illustration of the latter more rare form of this relation, I will read to you the histories, from notes taken by the resident physician Dr. Bruen, of two patients in whom it existed.

Case I.—Mary K., 39 years of age, married, was admitted to the Philadelphia Hospital on November 15, 1873. Both of her parents suffered from rheumatism and subsequent cardiac disease, and her mother died with dropsy, which came on after confinement. The patient herself had several attacks of rheumatism, but in other respects enjoyed fair health until about five months before admission, when she began to notice shortness of breath on exertion, together with œdema of the legs and ascites. At that time she was five months advanced in pregnancy. These symptoms grew slowly worse up to the time of her confinement, after which they continued to increase even more rapidly. Her labor was quite normal, and took place five weeks before her admission to the hospital. At admission her abdomen was enormously distended, the lower three-fourths were absolutely flat on percussion, and a marked sense of fluctuation was communicated to the fingers on palpation; the lower portion of the abdomen rested upon the thighs, and the friction of the opposed surfaces had caused extensive excoriation. The legs, from the feet upwards, were œdematous, and there was also some œdema of the hands and arms. The dyspnoea was so great as to render it almost impossible for her to lie down in bed; the respirations in the upright position numbered sixty per minute.

There was no evidence of any disease of the lungs or pleura. The area of cardiac dulness was increased, and a double mitral murmur, with an aortic systolic murmur, could be distinctly heard. The pulse was

feeble and frequent, beating one hundred and fifteen times a minute. The urine was found to be diminished in quantity, high-colored and acid in reaction, and to contain a large quantity of albumen, the precipitate by acid and heat being equal to at least three-fourths of the bulk of the fluid tested. The microscope revealed numerous *hyaline* and *fatty* casts. Her general health was much reduced, desire for food was almost absent, and her bowels were constipated.

She was ordered half an ounce of Basham's mixture* three times daily, twenty drops of tincture of digitalis, repeated according to its action on the pulse, small doses of elaterium to relieve the constipation, and a nutritious diet, with a small quantity of whisky (f3ij in twenty-four hours). Under this treatment the abdomen became somewhat less tense, a larger quantity of urine was passed, and the number of respiratory movements fell to thirty per minute, but the pulse remained frequent, and seemed to be unaffected by the digitalis, although its administration was pushed to the limit of safety.

This improvement was but temporary, and on November 20 it was decided to perform paracentesis. Six pints of a highly albuminous fluid were allowed to flow from the abdomen, when the canula was withdrawn and the aperture allowed to remain open. Two hours after the operation, the pulse, which had been beating one hundred and twenty per minute, fell to fifty, then to forty-six, and became dicrotic. The dicrotism was evidently cardiac in its origin, being produced by a second effort at systole on the part of the left ventricle. The patient was, however, in every respect better; indeed, felt quite comfortable. The effect on the heart and general condition was attributed to the digitalis, which was now, however, suspended.

November 24, the pulse was seventy-two, somewhat irregular, though entirely free from dicrotism; the respiratory movements were reduced to twenty-six, and were much more free, while the œdema was greatly diminished. She passed, on an average, three pints of urine each day. At this date the latter was found to contain an unusual number of mucous corpuscles, some spherical epithelium from the bladder, and a few *hyaline casts*; the amount of albumen was reduced to one-sixth of the bulk of the urine tested. Since the operation a large quantity of fluid, estimated at six pints, had trickled from the orifice in the abdomen. Quinine was added to the treatment.

Notwithstanding the continued use of diuretics (bitartrate of potash and infusion of juniper, infusion of scoparius, and free doses of digitalis), the ascites slowly increased, and on December 12 she was again tapped by Dr. Bruen, the resident physician, and one hundred and thirty ounces of fluid were removed. This was again followed by amendment, the œdema continuing to diminish. By December 22 the opening of paracentesis was closed, the *urine was free from albumen, and no casts were found after prolonged and careful examination.*

On December 24, after exposure to cold, she became much worse, and by December 25 the legs were again swollen almost to bursting, and had assumed an erysipelatos hue. The respirations were hurried, the skin was hot and dry, and the urine was so charged with albumen that it became almost solid on the application of heat and nitric acid. Paracentesis was performed for the third time, fifty ounces of fluid being removed. No relief was experienced from this operation: in fact, the dyspnoea steadily increased, and the pulse became

* R. Liq. Ammon. Acetatis, f3ij;
Tr. Ferri Chlor.,
Ac. Acet. dest., aa f3ij;
Curaçoe vel Syrupi q. s. ad fac. f3vi. M.

so feeble that it could scarcely be counted at the wrist.

At 3 P.M. on December 27 the pulse at the wrist was extinct and no cardiac impulse could be felt, but on auscultation the heart was found to be beating one hundred and thirty-nine times a minute. Upon extending the examination to the other parts of the chest, the physical signs of pleuritic effusion were detected on the right side. At 6 P.M., as a last resort, this side of the chest was tapped, and twenty-eight ounces of liquid removed; immediately afterwards the patient felt easier, but soon began to sink, and died at 9.30 P.M.

The general plan of treatment remained the same as that already mentioned throughout the course of the illness, although, as the indications varied from time to time, the quantity of digitalis used, as well as the form of its administration, was changed: as stated, other diuretic preparations, such as acetate of potash, juniper, sweet spirit of nitre, etc., were also tried.

At the *autopsy*, which was made twenty-four hours after death, a quantity of fluid, eighteen ounces by measurement, was found in the right pleural cavity, and the upper part of the parietal and visceral portions of the pleura was covered by a moderately thick layer of fresh lymph. The right lung was congested and somewhat compressed, but not at all inflamed. There was nothing abnormal in the left lung or pleura. The heart weighed fifteen and a half ounces. The left ventricle was dilated and hypertrophied. The leaflets of the aortic valve were thickened; this alteration was most marked along the edges of the leaflets and in the corpora aurantii; the latter were increased in size, being about as large as a split pea. Both leaflets of the mitral valve were thickened, and they were fused along their edges so as to form a funnel-shaped projection into the cavity of the left ventricle, with only a slit-like opening through which the end of the thumb could scarcely be passed; the valve thus coalesced was the seat of calcareous deposit. The right ventricle was also moderately dilated and hypertrophied; the pulmonary and tricuspid valves were healthy.

The liver weighed ninety-seven ounces, and was very fatty. The kidneys were lobulated, and weighed, together, fourteen ounces: they were, therefore, somewhat enlarged, and also congested; but in other respects they appeared normal to the naked eye. On microscopical examination, the renal tubules were in part lined with healthy epithelium, or with epithelium which was only slightly granular; in other portions, however, the epithelium was highly fatty. There was also slight increase in the interstitial fibrillar tissue. No trace of amyloid degeneration could be detected by the iodine test.

Case II.—William —, 51 years of age, was admitted to the medical wards of the Philadelphia Hospital on November 1, 1873. He had for a long time been an attendant about the hospital, and was very intemperate. At the time of admission he was suffering from dyspnoea, oedema of the legs, and ascites; and on examining the heart a double aortic murmur was detected. His urine, which was bloody and highly albuminous, contained casts filled with broken-down epithelial cells, granular casts, and casts containing blood-corpuscles. He died in one week: previous to this event, however, the amount of albumen and blood in the urine had greatly diminished.

The post-mortem examination revealed great thickening and calcareous degeneration of the leaflets of the aortic valve, while the aorta itself was extensively atheromatous. The liver was cirrhotic. The kidneys were turgid with blood, and therefore a little heavier than in health: in other respects they were normal, with the exception of a slight increase in the interstitial fibrillar tissue.

When the lesions brought to light by the post-mortem examination are considered in connection with the symptoms observed during life and with the previous histories, there can be no doubt that in each of these cases cardiac disease was primary, and that the alterations in the kidneys were brought about by the disturbance of the circulation thus produced. When the mitral or aortic valves are diseased, especially when the valvular leaflets become rigid or contracted so as to allow of regurgitation, there is always a tendency for the blood to accumulate on the venous side of the heart. Under these circumstances the movement of blood through the kidneys is retarded, these organs become greatly congested, and, although it cannot be said that an inflammatory process is set up, the simple increment of pabulum in the augmented supply of blood must encourage the production of an increased amount of interstitial connective tissue. This may in time undergo contraction. At any rate, these kidneys are but little enlarged, or they may remain normal in size, or may even be smaller than natural. When enlargement is present it is not usually more than can be accounted for by the large amount of blood present by engorgement. If the kidneys be smaller, this condition interferes with the entrance of arterial blood, reacting upon and causing further alteration in the heart, which in its turn produces greater structural change in the kidneys. Thus the change of action and reaction continues until the patient is carried off by the combined disease.

When the alteration in the kidneys is far advanced, the epithelial cells lining the renal tubules, being deprived of their proper amount of healthful nutriment, undergo fatty degeneration. This change, however, is rarely met with in comparison to the condition of increased connective tissue and contraction.

Further, a kidney which is constantly engorged with blood is much more liable to attacks of acute inflammation than one which is in a normal state. This fact explains the frequency with which, in cases of this nature, the urine becomes suddenly bloody and highly albuminous and filled with epithelial casts and blood-casts, even after very slight exposure, such as would produce no effect in a healthy individual. In the intervals between such attacks the blood-casts disappear entirely from the urine, and the epithelial and granular casts also become much less numerous and often disappear, the granular continuing longest. When the kidneys are so far degenerated that fatty casts appear in the urine, it is extremely rare for them to be absent at any time throughout the course of the disease. The patient whose history I detailed to you first is the only one in whom I have ever known fatty casts to disappear entirely, except in the albuminuria of pregnancy, in which it is not uncommon for all casts to disappear after labor. Another interesting feature in the same case was the more ready absorption of the digitalis after paracentesis was performed, and the prompt appearance of this physiological effect. This is to be explained on the well-known principle that osmosis is facilitated by diminished pressure. I have also observed it when venesection has been

practised during the administration of the drug; quantities which had apparently no effect before the operation displaying promptly, and even in an alarming degree, their effect upon the heart.

ORIGINAL COMMUNICATIONS.

ON SOME CASES OF NEGLECTED IRITIS.

BY H. S. SCHELL, M.D.

INFLAMMATION of the iris is one of those disorders which has long been well understood, not only by ophthalmologists, but by the profession generally.

Such, at least, is the usual impression. But the fact is that the disease in question is very often overlooked or mismanaged, and in consequence many cases may be seen in which, though the acute stage has finally subsided, the eye is left permanently injured: its functions can no longer be properly performed.

In some instances of this kind, vision may be interfered with by bands of false membrane crossing over or even occluding the pupil.

Or, although the pupil is clear, attachments may remain between the iris and the lens capsule, keeping the former in a smouldering fever of restraint, ready to burst out at any moment into a vigorous attack of fresh inflammation.

And this time the mischief may be so thoroughly done that the choroid, retina, and vitreous, one or all, are involved; and the vision impaired beyond hope of recovery; or the healthy eye may finally set up sympathetic action, and to save it we may be forced to remove the one first attacked.

Especially in iritis must we oppose the very beginnings, if we hope to effect a perfect cure; and it therefore becomes a matter of much importance to know why these earliest stages are so often ignored.

In very many cases, it seems probable that the violent congestion or inflammation of the ocular conjunctiva, which so generally accompanies the disease, is responsible for its obscurity.

And it is quite natural that it should be so. A person with a sore eye applies for treatment. His eye is painful, watering profusely when any attempt is made to examine it. The spasmodically-contracted lids are forced apart just long enough to disclose a crimson conjunctiva and a clear cornea, and the first impulse is not to subject him to the pain of a further examination, but to prescribe some cooling lotion or astringent drops, and let him go in peace.

The following is a case in point:

M. C., female, aged 39, came to the Eye and Ear Dispensary of St. Mary's Hospital on the 5th of August, 1873. Her right eye had been very painful for two weeks. She had consulted one physician who had given her an astringent wash, and afterwards another who had advised the constant application of a cold infusion of slippery elm bark. But these medicines had only caused an aggravation of her symptoms. Upon examination, an intense congestion was found pervading the conjunctiva; but

through the network of interlacing vessels could be dimly seen a rosy zone of radiating vessels surrounding the cornea. There was a well-marked phlyctenula just beyond the outer margin of the cornea; also great intolerance of light, lachrymation, and dimness of vision. The iris was of a dull yellowish color, while that of the sound eye was a bright gray. Under the influence of alternate light and shade the contracted pupil moved very slightly and sluggishly.

She was ordered, for local use, a solution of the sulphate of atropia and to take colchicum and Dover's powder. When she returned to the dispensary on the 8th, the pupil was dilated, but irregularly, showing two points of adhesion to the lens. Mercurial inunction, and iodide of potassium, gr. x t. d., were prescribed, and on the 17th the pupil was widely and regularly dilated, the pain and photophobia gone, and the eye apparently well, except the remains of the phlyctenula, which was shortly cured by the local application of calomel. The atropia, however, was continued for the remainder of the month.

In the following case, also, the conjunctiva had occupied more than its share of attention:

C. S., a married woman, aged 32, presented herself for treatment August 5. Her left eye had been sore nearly a month. During that time her physician had prescribed for her various eye-drops; had blistered her on the temple and back of the ear. Upon inspection, the conjunctiva was found deeply injected, the episcleral zone barely discernible, the iris dull, and its color changed from blue to green. A well-marked, brownish nodule, the size of a hemp-seed, projected from the surface of its upper and outer segment, and opposite this point the episcleral zone of vessels was better marked than elsewhere. A few drops of an eight-grain solution of atropia placed in the eye caused in the course of half an hour some irregular dilatation of the iris, showing the existence of a synechia behind the nodule and at the lower edge of the pupil.

Upon close cross-examination, no further evidence of venereal taint could be obtained.

A solution of atropia for local use and mercurial inunction were ordered.

On the 15th the gums were found to be spongy; the nodule on the iris had disappeared; there was slight hypopyon in the anterior chamber, and the pupil was regularly and widely dilated. She was ordered to discontinue the inunction and to take pot. iod. gr. xv t. d., also liq. morph. sulph. f3i p. r. n., for the relief of nocturnal pain. On the 5th of September she considered herself quite well.

There is another class of cases, where the conjunctiva is not at fault, but the condition of the iris is disguised by that of the cornea. And here it is well to remember that iritis is often the main and visible link in a chain of disorder with keratitis at one end and destruction of the choroid and the retina at the other.

An inflammation of the cornea is always accompanied by more or less injection of the small, straight radiating vessels around its edge; but whenever that ring of vessels is seen, suspicion should be aroused as to the condition of the iris, and a thorough examination of the latter should be made without delay.

L. S., a married woman, aged 40, applied for treatment on the 2d of September. Her left eye had been troublesome for a month, and had been treated with various drops and lotions without benefit. There was a general haziness of the cornea, with some dotted

opacity on its posterior surface, and a slight injection of the sclerotic vessels bordering the cornea. The naturally brown iris was of a somewhat more reddish hue than in the healthy eye, and the pupil responded not at all to the stimulus of light. A few drops of an eight-grain solution of atropia produced a scarcely visible effect on the pupil, which showed, however, no irregularity in its outline. The woman was apparently in the best of health, but said that her children were unhealthy, and that she had had several abortions. She was ordered to apply locally a four-grain solution of atropia three or four times a day, and to rub ung. hydrarg. 3i in each armpit night and morning. On the 12th, the pupil was fully dilated and the eye improved.

Pot. iod., gr. x t. d., was prescribed in place of the mercury. On the 4th of October she was apparently well.

And so one might go on, almost ad infinitum, with the recital of cases of this kind, in which the sufferer is finally forced to seek relief at the hands of specialists or to endure a vision permanently impaired. And yet no disorder of the eye is more certainly detected than iritis, if only a careful search be made.

A particular set of symptoms always accompanies the affection; but while some of these are always present, the others may vary in degree and even be entirely absent.

These symptoms are: 1. *Sluggishness of the pupil under the stimulus of light.* This is the most important test of all, and is present in every case. The want of mobility results from the congestion of the vessels of the iris and from effusion into its structure. As the disease advances, pseudo-membranous attachments form to the capsule of the lens, or bands extend across the pupil, or even fill it up and prevent all motion.

If the healthy eye is closed and the other alternately shaded by the hand and exposed to the light, we can generally arrive at a pretty good notion of the condition of the iris. If, however, any doubt remains, a few drops of a four-grain solution of atropia may be placed in the eye, and in some cases, where the secretion of tears is so great as to wash away the mydriatic almost immediately, it may be necessary to repeat the application in a few minutes. After the lapse of twenty minutes or half an hour the effect on the pupil may be quite evident to ordinary inspection. If not, we can take a lens of two and a half or three-inch focus, and concentrate the light of a lamp obliquely upon the pupil. A similar lens may now be used to examine the eye, and may show us perhaps little points on the anterior capsule of the crystalline lens, left by the iris in breaking loose from its false attachments; other adhesions not yet broken down; minute specks of plastic matter on the papillary margin; or a swollen condition of the whole membrane.

Unless absolutely necessary for purposes of diagnosis or treatment, it is, however, almost a cruelty to put a strong solution of atropia into the eye of a person who is obliged to depend upon that organ in his daily occupation. The intense glare of light which often results from the improper use of atropia is distressing in the extreme, and the paralysis of the accommodation renders vision practically useless for any kind of near work. The dilatation will

last in such cases for a week or ten days, to the great annoyance and alarm of the patient.

2. *Change of color.* This is sometimes the most striking symptom at first glance. The result is such as might be produced by the mixture of a reddish-yellow with the natural hue, though it is often disguised by haziness of the cornea, or turbidity of the aqueous humor. The change in the general appearance of the iris is aided by the fact that the bright and delicate radiating fibres which may be seen to compose the healthy organ become blurred and dull.

3. *Sclerotic zone.* The rosy zone of short, straight vessels surrounding the cornea and radiating from the pupil as a centre is always present in iritis. The irregular, branching vessels of conjunctival hyperæmia may overlie this zone, but do not often hide it entirely. We must look for it through the conjunctiva, and we are aided in doing so by sliding the latter membrane about a little with the fingers, so as to heighten the contrast between the movable vessels and the fixed ones beneath. If keratitis co-exists, the zone may be due to that affection, and we must look for other symptoms.

4. *Pain.* More or less pain about the eye is always present, especially at night. But this symptom is, of course, not peculiar to iritis.

5. *Intolerance of light* is seldom entirely absent. This condition, however, may depend on other pathological changes than the one under consideration, as may also—

6. *Dimness of vision.*

Attention to these symptoms will serve to detect any case of iritis, and in its ordinary or plastic form no other will be marked. But in the serous form there may be only slight injection of the episcleral zone, the conjunctiva may be unaffected, and, while the color of the iris is but little changed, the absence of mobility is sometimes complete.

In the gummatous form we have the symptoms of a syphilitic gummy tumor of the iris superadded to those denoting an inflammatory condition of that organ.

In regard to treatment, it is well to bear in mind that cold demulcent infusions and astringent washes only aggravate the disease. The conjunctiva, therefore, may be left to take care of itself, while energetic measures are directed towards the little membrane on which so much depends.

The sulphate of atropia is from first to last an indispensable remedy. If the alkaloid itself is used, a solution of sufficient strength can be obtained only by the addition of an acid, and it is very difficult not to get an excess of the latter, with a resultant solution which is highly irritating to the already inflamed conjunctiva. A solution of four grains of the neutral sulphate in a fluidounce of distilled water forms a perfectly bland application.

It is best applied by drawing down the lower lid and placing within it, by means of a pipette or a quill, a couple of drops every hour until the pupil is fully dilated or we find that it is firmly bound by synechia. In the latter case the atropia is useless, and should be suspended until the resolvent effects of mercury can be obtained.

It will also be futile to employ atropia in the beginning, if the grade of inflammatory action is very high, or the ocular tension is much increased. The former case will need a certain amount of derivative treatment, leeching of temples, purgation, etc., and the latter the performance of paracentesis of the cornea before the mydriatic can be absorbed.

When the pupil has been once fully dilated, it is often sufficient to use the atropia once, daily, to keep up its influence; but it may be instilled oftener, of course, should it be necessary. The object is to get and keep the iris in the condition of as small a rim as possible. Even after the case is apparently cured we find it is better to continue the local influence of the drug for a couple of weeks, or until there is no longer a suspicion of iritis; not persisting too long, however, as it appears to have a tendency to produce granular lids.

The pupil should be closely examined every day or two, and if adhesions are formed or forming, we should at once resort to the administration of mercury,—preferably by inunction. If the adhesions are recent they will generally yield to a smaller amount of mercurial than is necessary to touch the gums.

Morphia, in sufficient doses to allay pain, has a most beneficial influence on the course of the disease.

In any case, it is well to fill up the space around the globe, over the closed lid, with soft cotton, and cover with a bandage. This sets the eye at rest, and aids in the contraction of the vessels, by the warmth it maintains. But in bad cases compresses wrung out of hot water must be kept constantly applied until the most urgent symptoms are alleviated.

In every instance it will be necessary to find out the cause on which the affection depends,—whether traumatic, rheumatic, syphilitic, malarial, sympathetic with the other eye, or with some pathological condition of the system,—and to adapt the treatment to the circumstances. Cases which are obviously of rheumatic origin, and without much plastic effusion, are often readily subdued by the administration of Vance's pills, one of which contains ext. colchici acet., gr. $1\frac{1}{4}$, pulv. ipecac. comp., gr. iv: one to be taken before breakfast and dinner, and two at night.

In a large proportion of cases our suspicions will be directed to a syphilitic origin, and, however unjust this may often be, it is certain that mercury is frequently indispensable to the cure: so that it is generally better to give the patient the benefit of the doubt so far as the privilege of taking the medicine is concerned.

A CASE OF EXCESSIVE ERUCTATION.

BY ALONZO L. LEACH, M.D.

THE history of the following case is presented for publication because it bears upon interesting questions in physiology, and on account of the excessive character of the eructation.

John B., Irishman, æt. 28; laborer. At noon, July 7, while in the possession of excellent health, engaged in work that subjected him to the intense heat of the sun, he became suddenly prostrated. The perspiration,

at the time profuse, was checked; he experienced extreme weakness, with vertigo and headache. In this condition he was forced to retire to a shady spot, and towards evening returned home. The following day, the above symptoms partially disappearing, he resumed work, and continued until 4 P.M., when he was seized with another attack, differing from the first as follows: violent headache, vomiting, and *belching of wind*. The next day he persisted in his efforts to work, continuing to do so until nine o'clock A.M., when he was affected as previously, the eructation lasting until noon. He returned home; passing the remainder of the day and night free from eructation, with headache and general weakness. At six o'clock on the morning of the 10th the eructation came on, twelve hours after fasting, continuing throughout the entire day, relief being afforded at its close by medicine. In this condition he remained, passing gas at irregular intervals, until July 14, when at 10 P.M. an attack of eructation began, lasting through the night and the following day and night, when he fell asleep, completely exhausted, having spent two sleepless nights. On awakening, the eructation reappeared, and continued almost constantly (temporary relief being afforded at times by the administration of drugs) until the day on which I first saw him,—August 18.

At this stage of the disease I found him profoundly anæmic, with a cadaverous appearance, much emaciated, and an anxious countenance, presenting the appearance to a superficial observer of one laboring under some chest-trouble. The perspiration was standing in drops upon the face, which was unusually pale, the lips being livid. Respiration was performed with difficulty. Gas was constantly passing from the stomach with a peculiar and characteristic noise. In conversation he was frequently interrupted, and talked with difficulty, owing to the rapid and constant eructation. The gas was odorless and tasteless. He was unable to lie down, for fear of choking, and for a number of nights had not been able to sleep except in a sitting posture. He had eaten but little for days, and now everything he ate escaped from the stomach with the gas. From the date of his attack he had lost twenty-six pounds, and he was in an actual state of starvation. He was subjected to flashes of heat, followed by coldness. All of the symptoms were exaggerated and the patient seriously affected by his coming in contact with the sun's rays. Percussion showed the stomach enlarged and tympanitic. I placed the patient at once upon charcoal, with general and nerve tonics, the result being complete recovery.

Remarks.—The first point of interest to be noticed in this case is the peculiarity of the attack. This man, while exposed to excessive heat, became affected by it. The insolation was rather of an exhaustive type, in which nervous depression predominated. With the cerebral symptoms the eructation developed itself, and the interesting inquiry is, Was it of nervous origin? We think the sudden gastric symptoms, following so closely those of a nervous character, point clearly to the brain as the primary seat of trouble. The brain, suffering from depression, became incapable of supplying the stomach with a due amount of nerve-stimulus, and it, in turn, became disordered, or else the train of symptoms was developed by an unexplained sympathetic or reflex action. We have also favoring this theory the facts that the eructation was influenced by the patient's coming in contact with the sun's rays, and that local treatment gave but temporary relief, complete recovery not taking place until all nerve-symptoms had disappeared.

The second question of interest is, From whence did the gas originate?

According to authorities on diseases of the stomach, we have three possible sources from whence gas originates in that organ.

1. Air swallowed.
2. Gas generated from the food and secretions by decomposition or fermentation.
3. Gas secreted (improperly termed) from the blood.

In the case before us we exclude the first source, and pass to the consideration of the second, it being the principal source in all ordinary cases of eructation. Here we have, in the first stages of this case, eructation coming on hours after food has been taken, and, when taken, seeming not to be affected by it. Now, it is established that small quantities of food may give rise to large quantities of gas, and we might here account for the presence of the gas on the food-theory, and admit that a process of accumulation had gone on during the act of digestion, and that hours after one would have supposed the food properly digested and absorbed, the pressure became so great as to overcome the resistance at the cardiac opening of the stomach and the gas escaped. We go a step further, however, and reach a period in the case when the eructation was excessive and constant, when no food was taken into the stomach, except at times in small quantities and that being rejected, and when the patient was actually starving. How can we account for the gas being a product of the food at this stage? Doubting this source, could it have been due to changes in the secretions? Certainly not of a putrefactive character, for the gas was odorless. Possibly a fermentative change, for we must admit the presence of secretions, with little if any food on which to act. Could this gas have originated in the stomach at all? We confess our first thought was to accept this case as proving the blood-origin, but we find arrayed against such a theory many able writers on the subject,—among them Brinton, of England. Favoring this view of the case, we have a weakened stomach and capillaries admitting of a freer escape of gas, the constant eructation demanding an inexhaustible supply, a blood surcharged with gases from the enormous waste of tissue, etc., etc.

In conclusion, does not this case agree with the celebrated experiment of Magendie, and favor the doctrine taught by many physiologists and writers on diseases of the stomach,—that gas may be excreted by that organ? Aside from these questions, the case is one of interest.

2118 SPRUCE STREET, PHILADELPHIA, March 19, 1874.

IMPACTED GALL-STONE (*The Clinic*, February 14, 1874).—Dr. Confer reports the case of a man, æt. 45, who died in consequence of an impacted gall-stone which was found firmly fixed in the cystic duct. His last sickness was of six days' duration, during which time there were persistent nausea and vomiting, with great tenderness of the abdomen, obstinate constipation, scanty urine, etc., but not the slightest discoloration of the skin or conjunctivæ, jaundice having been entirely absent.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

Reported by Dr. JOHN M. KEATING, Resident Physician.

FACIAL ERYSIPELAS.

IT may not be uninteresting or devoid of some practical information to present two cases, the termination of which was rather different from that generally seen in epidemics of facial erysipelas.

Case I.—T. W., aged 48, a hard drinker, entered the Philadelphia Hospital on the evening of the 10th of February. For more than a week he had been exposed day and night, while under the influence of liquor, sleeping upon cellar-doors, and deprived of proper food and clothing. He stated that four days previous he noticed upon the bridge of his nose a red patch, which extended rapidly until, when his friends brought him to the hospital, the whole face had become involved. When first seen, his temperature was $104\frac{3}{4}^{\circ}$; his face very much swollen, particularly about the upper lip and nostrils; there was some swelling also of the mucous membrane of the nose. He complained of great tension of the scalp, and pressure upon it would cause him to complain, even during the delirium, which became so troublesome as to require the nurse to strap him to his bed to prevent his wandering around the ward. The pulse was hard and quick (120). His general condition denoted the great prostration which always accompanies such diseases in drunkards.

He was ordered a tablespoonful of Basham's mixture (containing fifteen drops of tinct. ferri chlor.), with one grain of quinine every two hours, plenty of milk and beef-tea, alternating every hour; also, an external application of—

R Camphor. resin., \mathfrak{z} i;
Unguent. hydrarg., \mathfrak{z} ii.

The bowels were opened by one-sixth of a grain of calomel every hour until they were gently moved; a dose of castor oil was then administered.

Evening of 20th.—Was very delirious all day, had to be strapped in bed; drinks as much milk as he is allowed, constantly asks for it. Ordered three grains of quinine every three hours. His temperature fell this morning to 102° , and still keeps so; pulse 100; no lung-complication; no albumen in urine.

February 22.—The night-nurse reports that he slept well after he had taken one-quarter of a grain of morphia, which was ordered at midnight.

February 24.—Continues as usual; is very weak; the pulse has been varying from 100 to 120; the temperature has been gradually diminishing; on the morning of the 21st it was 101° ; in the evening, $101\frac{1}{2}^{\circ}$; morning of 22d, $100\frac{3}{4}^{\circ}$; to-day it is exactly 100° . The swelling of the face is subsiding. There is aphonia and some cough, with swelling of the mucous membrane of the pharynx, which is coated with a tenacious, grayish exudation. Inhalations of lime-water and paregoric are repeatedly given, with a gargle of chlorate of potash and tincture of cinchona. There is no lung-trouble. An enema of castor oil and turpentine was given to counteract the tympany, from which he suffers much. The delirium still continues. The whisky, which he has been taking since the 22d, was increased to one ounce every three hours, as milk-punch. Stopped Basham's mixture, and ordered simply twenty drops tinct. ferri chlor. every two hours, with two grains of quinine every four hours, and small repeated stimulant doses of tinct. opii deod.

February 26, morning.—Not quite so delirious; rested better last night; bowels have not been opened since last note; one-eighth of a grain of calomel every hour

during the day ordered, to try to resolve the membrane in the throat, and also to relieve the bowels. The deposit seems to impede respiration. The lungs are still clear. After each inhalation strips of false membrane come away, leaving a raw surface.

February 26, evening.—Crepitant râles, together with sibilant and sonorous ones, are heard over right chest. Since yesterday he has been taking half an ounce of whisky every hour; ten grains of carbonate of ammonia are added to each second dose. Poultices to chest seem to afford but little relief. Died at 2 o'clock A.M.

Post-mortem, seven hours after death. Before taking off the calvaria, there was no redness of the membranes, but some subarachnoid œdema was noticed. There was no opacity of the membranes at the base, but some basilar effusion, and more liquid than usual in the ventricles. There was decided venous congestion; the veins at the base of the brain standing out prominently, well filled. Quite an extensive deposit, resembling that seen before death upon the tonsils, was noticed, upon detaching which it was found to cover portions much ulcerated. The mucous membrane of the pharynx, larynx, and trachea was swelled and inflamed. The bronchial tubes red, and containing frothy mucus. The pleuræ of the right lung were adherent with freshly-exuded lymph; the lung itself, solid anteriorly, and œdematous posteriorly. The heart contained ante-mortem clots.

Case II.—Mary S., aged 32, a native of Germany; had previously been pretty healthy; was an assistant in the surgical wards of the hospital during the cold weather, and had consequently been exposed to variations of temperature for some time. On the 20th of December she was sent to the medical floor, complaining of cold in the head, with its usual concomitants of fever, headache, and nasal discharge. She was put to bed, the routine treatment adopted of diaphoretics, etc., with the addition of quinine in small doses. Two days afterwards, a small red patch made its appearance on the right ala nasi, which extended rapidly, and soon left no doubt as to the correctness of the diagnosis of facial erysipelas. Twenty drops of tinct. ferri chlor. were ordered every two hours, her bowels opened, quinine (twelve grains daily) given, and a dressing of ten grains of sulphate of iron to the ounce of water, frequently changed, applied to the face. The inflammation extended rapidly, and soon spread over the entire face and neck.

On the sixth day she complained of headache. Her temperature was never above 103° ; her pulse quick and wiry.

On the 1st of January I assumed charge of the ward, and found her condition as just described. Her face was caked and dry from the iron solution; her bowels had not been opened for nine days, and her state altogether pointed to anything but a favorable prognosis. Mucilage of slippery elm was now used externally, one-sixth of a grain of calomel given every hour until her bowels were moved, and followed by a dose of oil. The quinine and iron were diminished, and nourishment in the form of milk, beef-essence, etc., was given at stated intervals. She had a severe laryngeal cough, with much dryness of the throat, which was controlled by atomization with paregoric and lime-water and cracked ice. But the headache, which was supposed from her general condition to be due to this, did not disappear. Crackling râles of hypostatic pneumonia were heard posteriorly. On the 3d she became delirious, but at intervals she could be aroused, when she complained of her head. Towards evening she was seized with convulsions, which began with twitchings of the right side of the face, then the left, and finally the whole body became involved. During these attacks the pulse was strong and hard, at other times quick and irregular;

pupils contracted. Wet cups were applied to the nape of the neck, cold cloths to the head, an injection to move the bowels freely, warmth to the feet, etc., but all were of no avail: she died that evening.

A post-mortem was made early next morning, with the following result:

Hypostatic congestion of the skin more marked in places which had been occupied by the inflammation, though noticed elsewhere; the face was pale; left lung adherent with freshly-exuded lymph; the pleura markedly inflamed; right side normal.

Hypostatic pneumonia posteriorly of both lungs, with much œdema; bronchial mucous membrane red and swollen, and frothy mucus in bronchial tubes; right auricle filled with a large adherent ante-mortem clot, which extended into the ventricle and pulmonary artery. A similar one was seen on the left side. The dura mater was rather pale, and not adherent; the membranes at the base were decidedly opaque, particularly around the medulla oblongata, pons, and cerebellum. In the sulci of the brain posteriorly there was a serous exudation, but towards the anterior portion this was replaced by a gelatinoid substance beneath the pia mater, which in places was about one-tenth of an inch in thickness. Where the deposit rested upon the brain the surface was pale; at other portions beneath the membranes there was marked congestion. The ventricles contained but little fluid.

The principal points of interest in these cases were the extension of the inflammation inwards, the total failure of treatment, and the gloomy prognosis which they teach in all such cases, where there is much brain- or lung-involvement. A number of cases of this disease have been treated here during the past quarter, presenting different types and complications. The usual treatment adopted was a supporting one mainly, commencing with an emetic or purgative, immediately followed by iron and quinine in rather large doses, milk, beef-tea, etc., and stimuli, when indicated by great exhaustion or previous habits. The local application which seemed to be most grateful was either oxide of zinc ointment or cloths of lead-water and laudanum. In four of the cases whose temperature-record was accurately kept, the maximum was reached on the third or fourth day. A sudden deflorescence succeeded this, and within thirty-six hours from the maximum (forty-eight at the utmost) the temperature became normal, or even went below it, in one case to 97° , and in another to 96° . In one case, that of a young girl, in whom there was no complication, the maximum was reached on the evening of the sixth day, and by a gradual deflorescence the temperature was $98\frac{1}{2}^{\circ}$ on the eleventh day. Of course the number of cases here quoted is too few to establish a precedent. The main object in speaking of them is to show that a very gradual descent in the temperature-curve does not always denote a complication, but that a serious complication may exist without an extraordinarily high temperature.

TRANSLATIONS.

TEMPERATURE OF THE HEART AND LUNGS.—Ed. Albert and S. Stricker assert (*Wiener Med. Jahrbücher*) that when measurements of the temperature of the heart are made by introducing the thermometer into the cavities of the heart, so that it is exposed to the blood, the results obtained are not accurate, since the instrument is influenced both by the temperature of the heart and by that of the blood. To avoid this source of error, they inserted the bulb of the thermometer into a pocket in the muscular tissue of the heart, and found that they

obtained in this way a temperature 0.5° to 0.7° C. higher than that given when the bulb was only placed in contact with the surface of the inner wall of the ventricle. The supposition that the temperature of the substance of the heart is higher than that of the blood (at least in the left ventricle) was confirmed by a second experiment. A thermometer was passed from the aorta into the ventricle, and a difference of but 0.1° in favor of the temperature of the blood in the heart was noted; but after death a difference of 1° between the temperature of the ventricle and its contents was noticed.

The right auricle was found to be higher in temperature than the descending cava, and the right ventricle still warmer than the auricle, while the temperature in the ventricle rose as the apex of the heart was approached. The differences in temperature were not removed by ligation of the ascending cava, but were in some cases increased. The variations in the right ventricle are not due alone to the higher temperature of the ventricle, but also to the lower temperature of the blood of the descending cava as compared with that of the ventricle itself. It was supposed that the blood of the descending cava was warmed by the blood of the coronary veins, and this was proved by measurements of the temperatures of the blood in the descending cava and the pulmonary artery respectively, the ascending cava having been ligated. They found, also, that the temperature of the blood in the pulmonary veins is lower than that of the blood in the descending cava, and conclude from this that the blood is cooled in its passage through the lungs. There is, however, an element of doubt as to the temperature of the blood in the pulmonary veins, for as the thorax was opened it is possible that the temperature of the lungs was thus lowered, and with it that of the blood contained in them. W. A.

ACUTE YELLOW ATROPHY OF THE LIVER IN PREGNANT AND LYING-IN WOMEN.—A. Dupré (*Centralblatt für die Med. Wissenschaften*) recently had the opportunity of observing the post-mortem conditions found in three cases of poisoning by phosphorus and one case of acute yellow atrophy of the liver. The patients who were poisoned with phosphorus were children aged from ten to fifteen years; the one who died from the disease of the liver was a young woman of eighteen years, who had recently been confined.

In the livers of the first three cases he found a disposition to an enormous formation of fat, there being in the most advanced stage fatty infiltration of the entire parenchyma of the organ, and finally absorption of the fat which became free by bursting of the liver-cells, but there was no proper destruction of the tissues of the liver. In the acute yellow atrophy there was found parenchymatous inflammation, and in some places there were also evidences of interstitial inflammation. He has sometimes noticed fatty infiltration in addition to these changes, but this is by no means constant or characteristic. The results of these changes are molecular degeneration and metamorphosis of the hepatic tissues into a finely granular detritus, often mixed with molecules of fat. Dupré, therefore, regards the parenchymatous inflammation of the cells of the liver as the essential characteristic of this disease, from which pressure upon the smaller gall-ducts results, producing icterus. As in all glands, obstruction of the ducts causes a degeneration of the cells, and they undergo fatty atrophy. W. A.

THE INFLUENCE OF DIGITALIN ON THE BLOOD-PRESSURE OF MAMMALS.—R. Böhm (*Dorpat. Med. Zeitschr.*) maintains his former conclusion that the increased blood-pressure consequent upon the administration

of digitalin can be explained only by assuming an increased energy of the heart's action.

After section of the medulla oblongata in cats and dogs, care being taken to avoid injury to surrounding parts, the blood-pressure is diminished by about one-third of its force. If digitalin is injected into animals that have been thus operated upon, but a slight increase in pressure is produced: a return to the normal amount is never noticed. In order to disprove the assertion of Ackermann that the increase of pressure in the arterial system after the administration of digitalin had a peripheral origin,—namely, contraction of the peripheral arteries and more especially those of the abdomen,—Böhm, after section of the medulla oblongata, ligated the thoracic aorta above the origin of the great abdominal vessels. After this had been done there was for some time a variation in the amount of pressure, which soon, however, became fixed at a point almost normal. If injections of digitalin were made in animals under these conditions, the pressure increased, and the contractions of the heart became more powerful; a diminution in the energy of the heart was first noticed when the doses of digitalin were markedly increased. The increased blood-pressure due to the administration of digitalin is caused only by increased energy of the contractions of the heart.

CAUSES OF THE PATHOLOGICAL CHANGES IN THE LUNGS CONSEQUENT UPON SECTION OF BOTH PNEUMOGASTRIC NERVES.—A. Genzmer (*Pflüger's Arch.*) draws the following conclusions from a series of experiments which he has been making, relative to the influence of the section of the par vagum on the lungs: 1. The change in the activity of the heart caused by section of the par vagum has no influence upon the condition of the lungs. 2. Edema of the lungs does not follow the constraint in breathing due to paralysis of the recurrent laryngeal nerves. 3. The entrance of saliva into sound lungs does not cause the change noticed after section of the pneumogastric nerves. 4. Hyperæmia and oedema of the lungs occur after section of the par vagum when no foreign bodies (as saliva) find entrance into the bronchi. 5. Paralysis of the branches of the par vagum distributed to the lungs causes a pathological change in the tissues of the lung. Paralysis of the same nerve-branches of one lung causes characteristic changes, especially a marked hyperæmia, and this, together with the diminished power of resistance of the lung, allows a second cause of irritation, as the entrance of saliva, to produce the characteristic changes. W. A.

THE INFLUENCE OF THE ACTION OF THE SKIN ON THE SECRETION OF URINE.—K. Müller reports (*Arch. für exper. Path.*) the results of some experiments conducted by him in Claude Bernard's laboratory, upon large dogs, in reference to this subject. The dogs were narcotized and operated upon, so that the urine could be collected as it came drop by drop from the ureters. Six experiments were made with ice-cold compresses, upon dogs which had previously been shaved, and it was found that the amount of urine secreted was increased from twenty-three to fifty per cent. This increase was not noticed until the application had been made for some ten to twenty minutes. Three experiments were made with warm compresses, and by baths of water at the temperature of 40° C., with the result of diminishing the secretion 17 per cent. Mustard plasters and blisters were allowed to remain for thirty minutes, but produced no change; and in three cases out of seven in which the skin was varnished, but a slight diminution in the amount of secreted urine was noticed. PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 18, 1874.

EDITORIAL.

THE USES OF HOSPITALS.

IN a recent editorial we endeavored to enforce the axiom that those who have opportunity have also responsibility; that the hospital physician owes it to himself, owes it to his brethren, and owes it to humanity, that he advance in some way our knowledge of healing. It is urged in answer that it is not every even good practitioner who has the ability to do this. Of course not; we can't all be cream; but we do object to the skim-milk rising to the top and usurping the place of the cream. Any man who for a succession of years holds a hospital position and does not add anything to the common stock, ought to be skimmed off: which is the long and short of our story.

As our hospitals are organized and furnished, however, even a Hunter or a Louis could do little or nothing, unless he had abundant leisure or had the pecuniary ability to pay, as some of our hospital physicians now do, a younger man to take notes of his cases. But clinical clerks are only a small part of what is needed. A fitly-furnished hospital should leave its staff no excuses in the direction of lack of help and instruments; whilst, so far as we know, there is not in the city of Philadelphia to-day a single general hospital thoroughly furnished with all the important modern instrumentalities *for the treatment of disease, let alone for its investigation.* What folly, then, to blame the staffs for accomplishing so little! Is it not a farce to expect Philadelphia to maintain its prestige when not a single

general hospital in its confines has a properly fitted-up electrical room, and when not a general or a special hospital in its limit has proper bathing facilities? Is it a wonder that our glory is departing, and that already "Ichabod" seems lambent over us?

We doubt if any of our hospitals have more than a pretence of a laboratory, and we know of none that has well-appointed dissecting-rooms.

Will the new school hospitals remedy these things? Let us hope that the first good work they accomplish will be the shaming of our managers into thoroughly furnishing the institutions under their care. Surely, if our new hospitals do not redeem us, we may well join in the goblin's cry of "Lost! lost! lost!"

No amount of apparatus, however, it seems to us, will be of much use so far as the study of disease is concerned, unless some new plan or plans of organization are adopted. Take as an evil example of the present system the great city hospital. Its attending staff contains men of marked ability. Its wards overflow with such chances as have made the wards of La Salpêtrière famous through the work of Charcot and his scholars; but the younger physicians come to it fresh and utterly untrained, so that probably not one man in twenty could take, on entering the wards, clinical notes of the least value. Before they have become trained to this duty, which is not imperative upon them, and which they may or may not care to fulfil, a new set succeeds them, and the same wearisome drill is to be gone over once more. The system may be very well as a means of training medical apprentices, but it imposes needless duties on the attending staff, and places sad obstacles in the way of fruitful work. What we want is a set of intermediate men, who shall come between the heads of wards and the fresh hands; men who shall be more permanent, and a part of whose duties shall be to relieve the attendants-in-chief and to follow out under their directions such lines of study as they may plan. Neither should any hospital lack the constant aid of at least one well-prepared chemist, since it is out of the question to look for knowledge of this kind in young physicians untrained to laboratory work; yet we doubt if even to-day there is one available man in Philadelphia capable of making an analysis of blood.

The organization of the new University Hospital is completed, at least on paper; and whilst it is certainly much better than that of any of the older institutions, we think it will have to be modified before it will be anywhere near perfect. The plan of the organization is as follows. There are general, surgical, obstetrical, and medical wards, and

certain special wards,—at present four in number. The resident staff consists of four members: two chief residents, and two assistants. The assistant obtains his position by a competitive examination, and at the end of six months, if he has given satisfaction, is promoted to the position of resident; the whole term of service being one year. As the hospital cannot possibly open with more than a hundred beds, this arrangement is perhaps the best that can be made, since more than four residents could not be maintained with justice to the charity. The assistant acts as clinical clerk, and as an assistant to the resident, who is responsible to the visiting medical officers. Owing to the service being so broken up into specialties, it is evident that when the hospital becomes larger the present organization of the residents would give rise to endless confusion,—two or three of the chiefs wanting the attention of one resident, it might be, at the same time. Fortunately, the right and the will to alter the arrangement as circumstances demand it both exist. It has occurred to us that if, when the hospital is capable of six residents, the time of service were lengthened to eighteen months, so that a resident should serve six months as assistant in the general wards, six months as full resident there, and six months in charge of special wards, the peculiarities of the case would be well met. But let this pass. We are not advocates of any special plan of organization. What we want to see recognized in the new hospital is the principle that all proper facilities for original work should be furnished, and that the performance of such work should be a recognized part of the duty of the staff.

TO those practitioners who see a large number of patients daily, and are not blessed with a remarkable memory, we can commend very highly the office and pocket Case Record Books of the Case Record Company, of Cincinnati, as nerve-saving machines, and as tending to certainty of practice. They are simply blank books, conveniently printed, and arranged so that on one part of the leaf the doctor writes the prescription to be torn off, and on the other copies this, and, if he chooses, fills up a short formula, so as to constitute a brief history of the case.

WE are glad to see that the medical staff of the Orthopædic Hospital have profited by our counsel, and have instigated the board of managers to take their "before and after treatment" woodcuts out of their annual reports.

THE homœopaths will soon be following the lead of Prof. Clinkscales of the eclectic faculty, in asking, Who and what are we? We observe that out of eleven medical books reviewed in the *Ohio Medical and Surgical Reporter* (homœopathic) for January and March, eleven are standard works of the regular profession,—all of them either already noticed or about to be noticed in the pages of the *Times*. In nearly every case our homœopathic contemporary recommends these works very strongly to its readers. Verily, homœopathy is passing away: in the downward path after the stage of delusion comes the stage of fraud.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, MARCH 12, 1874.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

DR. JOHN H. PACKARD presented a specimen of *mammary cancer* from Mrs. T., æt. 70, English, mother of six children, only two of whom lived to adult age, and they died of consumption. Her last confinement was twenty-five years ago. Lactation was always normal, without abscess or other difficulty.

The present growth made its appearance as a very small knot, a year or two ago. It began to enlarge rapidly, and occasionally to give her pain, about four months ago. General health perfect. The growth—about the size of a lemon—and the atrophied gland were removed, by operation, March 3, Dr. L. Starr giving ether, and Drs. John Ashhurst, Jr., and Brinckle being present and assisting Dr. Packard. Three or four vessels were secured by torsion. The wound was closed with hare-lip sutures, and carbolized cerate applied.

The case has done well.

Dr. PACKARD also presented the *arteries from the brain of an apoplectic*. Mr. S., æt. 47, seemed in perfect health on the morning of March 5. At 12.30 he was found insensible in the water-closet, at a hotel.

When seen by Dr. Taylor he was partly conscious, though unable to speak. Pupils not markedly abnormal. When asked if the cold applied to his head felt good, he nodded; and when asked where he had pain, he put his right hand under the back of his head. The left arm and leg seemed paralyzed; the exact degree was not noted. His pulse was feeble, his surface pale and cold, and he seemed in a state of collapse. He swallowed two teaspoonfuls of whisky.

When Dr. Packard first saw him, his face was pale, his breathing stertorous; pupils contracted equally; occasional strabismus, and he was totally unconscious. Sinapisms were ordered, also stimulating injections; ice to head, and afterwards cups to back of neck and temples. Reaction took place; great heat of skin; pulse full and tense; right pupil now became dilated; left contracted. He was bled from the arm to about ten ounces, without any effect but to lower the pulse. Death occurred about ten hours after the seizure.

Autopsy, sixty-one hours after death. Head only examined. Some decomposition had occurred. Vessels of the dura mater much congested. A large quantity of coagulated blood effused beneath the pia mater at the

base of the skull, extending up on the outer surface of both cerebral hemispheres, and dipping into all the anfractuositities. The clot seemed to extend down along the spinal canal; it filled the third and fourth ventricles, as well as the right lateral ventricle, which was enormously distended by it. The left lateral ventricle was full of bloody serum.

Several vessels seemed to run through the clot in the right ventricle, and to one of them was attached a small firm bilobed body.

The brain-substance was universally softened; but whether this was a post-mortem change or not, was not apparent.

Dr. R. M. BERTOLET exhibited specimens of *multiple gummata of the cranial bones and dorsal vertebrae, giving rise to extensive destruction of these structures, leading to compression of the spinal column and inducing paraplegia.*

"The accompanying skull and spine were removed from the body of a patient who died at the Philadelphia Hospital. Owing to the low condition of the man when admitted, and to the fact that he was unable to speak any but his own language, very little could be ascertained as to his previous history. Drs. Miller and Keating, resident physicians to the hospital, have, however, kindly furnished me with the clinical records of the case, from which the following summary has been made:

"Edward Paulisky, æt. 34, a native of Poland, was admitted into the hospital October 14, 1873. He complained of dull pain in the back, and of obstinate constipation. Stated that he had had gonorrhœa several times, and when quite young had a sore on the penis. Did not recollect having had any secondary manifestations. In all other respects had been a very healthy man.

"The patient was at once put upon iodide of potassium, and improved somewhat for several weeks. In December he began to complain of pain in the region of the kidneys, and tube-casts were detected in his urine. He was then placed under treatment for his renal troubles, the iodide of potassium being discontinued. During the following month the pain in his back became so intense that he was carefully examined for aortic aneurism; but no evidences of such a condition could be detected.

"About six weeks before his death (February, 1874), gradual loss of both motion and sensation was noticed in both legs, finally amounting to complete paraplegia. The obstinate constipation persisted throughout, but the bladder was controllable.

"No further records of the autopsy were preserved than these specimens, yet they in themselves are of sufficient interest to merit further study. The skull, which is so freely riddled with more or less complete perforations of various sizes, presents no other evidences of syphilitic alterations than those occurring in the immediate neighborhood of the gummata. Many of these growths can still be seen hanging loosely in these circular cavities, while the peripheral bony margins show an inflammatory process of hyperostosis and sclerotic thickening to be going on. A directly opposite process, leading to rarefaction and atrophy of the bony structures, has been induced in the centre by the pressure of the gradually-expanding tumors. At numerous points, where the perforation through both compact bony layers is incomplete, it will be seen that the erosion extends now more towards the external periosteal surface, while at other places again the pressure of the gummata has evidently been greatest in the direction of the cranial cavity, leading to absorption of the endocranial plate, the external covering remaining intact. There can be little question that in this instance the seat of these syphilitic gummata has been in the diploë, and not subperiosteal, a fact which goes far towards explaining why

their presence was not manifested during life, neither by any elevations beneath the integumentary coverings, nor by any ulcerations in the same.

"Upon the anterior surface of the spinal column no less than six large, round, circumscribed tumors are seen. Their presence in this situation has likewise given rise to extensive destructive inflammation. The second dorsal vertebra has been almost completely broken down, permitting a very decided bending of the spinal column at this point. The presence of one of these growths upon the surgical neck of the third rib upon the right side has led to such extensive destruction that a fracture at this portion of the rib has occurred.

"Upon the posterior aspect of the spine but two of these tumors are seen: one is situated upon the left side of the fifth and sixth dorsal vertebrae, the other upon the right side of the ninth. At both points the growths protrude so far into the cavity of the spinal canal as to press firmly upon the spinal cord. In the latter, extensive gray degeneration of the posterior and lateral columns has taken place. The microscopic appearances of these alterations will be described upon a future occasion.

"The sections of the gummata show, at many points, commencing cheesy degeneration. Sections made through specimens hardened in bichromate of potash show that there is a concentric arrangement around the thickened blood-vessels of the highly corpuscular parenchyma of the tumor. Bands of connective-tissue fibres are seen coursing through the field at wide intervals, the interstices between them being completely filled with the small, round, corpuscular elements."

The PRESIDENT said it was on a single occasion only on which he had examined the patient. He was then confined to bed, and complained of intense lumbar pain radiating along the lumbar plexus of nerves. He had understood the man to be syphilitic. There was abnormal pulsation of the abdominal aorta, but he concluded that it was due to mere irritation of the vessel. There was no distinct tremor, or bruit, or thrill, and there was no increased size of the artery. The man was at that time also feeble in his limbs, but there was no complete paralysis. Subsequently he learned that there were unilateral anæsthesia, and motor paralysis, and that the case terminated in convulsions.

The PRESIDENT also asked Dr. Bertolet whether gummata originating in the diploic structures of bone were much more rare than those springing from the subperiosteal tissues.

Dr. BERTOLET said they were more rarely met with; that those gummata characteristic of protracted syphilis and hereditary syphilis manifest themselves in the medullary portion of the bone; whereas in the more recent cases attended by roseola and the papulous syphilides we have usually the periosteal gummata.

Dr. BERTOLET also exhibited a specimen of *epulis*, and said, "It is through the kindness of Dr. Thomas Stellwagen that I am enabled to exhibit this tumor to the Society. We have here a bicuspid, removed from the lower jaw, to which a fragment of the alveolar process is seen firmly united. The tooth was removed from a middle-aged lady, and with its extraction ended what had been, no doubt, a very bad toothache, for there is attached to it a pear-shaped, distinctly nodulated growth, which upon closer inspection is found to arise not from the tooth, but from the periosteum of the adherent bone.

"The tumor is half an inch in length, and measures a quarter of an inch in diameter at its widest part: it is covered with a dense capsule of connective tissue, which at a few points is beginning to undergo calcification. The interior of the growth is filled with a soft, reddish substance, throughout which an imperfectly radiating, denser substance can be seen by the unaided eye.

"The microscopic examination shows the structure to be composed of round nucleated cells, many seen as apparently free nuclei; there are also present numerous giant or myeloplaxic cells, *i.e.*, irregularly-shaped parent-cells of enormous size, containing each from five to twelve daughter-cells. Spindle-shaped cells are also seen, but the round-celled variety predominates. Of these appearances, the existence of the multinuclear giant-cells alone suffices to disclose the sarcomatous nature of the epulis. The fact that the so-called epulides belong to the class of sarcomata was first pointed out by Virchow. They are more frequently found upon the lower than upon the upper jaw, where they may attain, when not interfered with, quite a considerable size. It is seldom that these growths are seen at such an early period of their existence and removed with the same facility as happened in this instance. The interest attached to this specimen lies in the fact that although the tumor unquestionably starts from the periosteal layer of the bone, yet its growth has been inwards at the expense of the cancellous tissue, which has been partially absorbed, and a cavity formed, out of which the tumor is readily lifted. The base of the tumor being opposite the neck of the tooth, it becomes an easy matter to conceive how the less-resisting cancellated structure necessarily first yielded to the gradual expansion of the tumor, which was thus made to assume a position as though it were a central osteo-sarcomata, when in reality it pertains to the periosteum and not to the medullary portion of the bone. The presence of the multinuclear giant-cells does not in the least militate against the view of the periosteal origin of the tumor, since they are found in the periosteum as well as the intraosseous sarcomata of bones generally."

The PRESIDENT presented a specimen of *enormously distended stomach, in connection with caseous consolidation of the left lung, with several abscesses simulating pneumothorax.*

Patrick Quirk, æt. 45, had been under observation for over a year, suffering with aggravated diabetes mellitus. It was found impossible to restrict his diet, and he habitually ate and drank most inordinately. A few months before his death, symptoms of pulmonary disease appeared, and rapid consolidation of the left lung followed. A little later, the physical signs of a cavity in the left mammary region were detected. At this time his morbid craving for food and drink rapidly diminished, and the amount of urine to the proportion of sugar fell. Some days afterwards it was noticed that the dullness which had been present over the lower lobe of the left lung was replaced by large, metallic, tympanitic percussion-resonance, extending from the base of the thorax up to the fourth intercostal space. The quality and volume of this tympany were carefully compared with the resonance over the left hypochondrium, and appeared distinctly different. There were also amphoric breathing and vocal resonance over the antero-lateral part of the left chest, below fourth rib; distinct and very constant metallic tinkling, and marked succussion-splash. These signs evidently suggested pneumothorax, and the sign which chiefly opposed the idea of its presence was the existence of numerous bubbling râles heard apparently superficially over the entire antero-lateral region of left chest.

The diagnosis of pneumothorax circumscribed below the level of the fourth interspace was determined upon. The patient rapidly sank, and died.

At the autopsy, the chest and abdomen were opened, and the organs examined *in situ*. The left lung was solidified throughout from cheesy infiltration, with four abscesses of considerable size,—two in the lower part of the upper lobe, and two in the lower lobe. There was no pneumothorax; but the pleuræ were in contact throughout, and were, in parts, coated with fresh lymph.

The right lung was comparatively healthy, containing but a few scattered nodules of cheesy deposit.

The stomach was enormously distended with gas, and pressed very forcibly up into the concavity of the diaphragm.

It was evident, therefore, that the phenomena above described, which so closely simulated pneumothorax, and which occurred in a case when pneumothorax might have been expected, were dependent upon an enormous stomach, in connection with a consolidated lung, the seat of several abscesses of considerable size.

Dr. H. LENOX HODGE asked whether the stomach was unusually distended by gas.

The PRESIDENT said not at all, except in this instance of sudden distention with flatus, which must have occurred between two of his visits. After this, the man was much oppressed, but did not refer to stricture of the stomach. He had little appetite or thirst; there was no eructation of gas. He was, moreover, at this time dull in intellect, and a very small quantity of opium now acted as promptly as a much larger quantity at an earlier period.

Dr. W. W. KEEN read a paper on *chlora* as preservative of anatomical and pathological tissues (published in the *Medical Times* for March 21, 1874).

REVIEWS AND BOOK NOTICES.

THE SPHYGMOGRAPH: ITS PHYSIOLOGICAL AND PATHOLOGICAL INDICATIONS. The essay to which was awarded the Stevens Triennial Prize by the College of Physicians and Surgeons, New York, April, 1873. Two Hundred and Ninety Illustrations. By EDGAR HOLDEN, A.M., M.D. 8vo, pp. 169. Philadelphia, Lindsay & Blakiston, 1874.

We confess that, after considerable experience with Marcy's Sphygmograph in the wards of a large general hospital, we have come to look upon it as a kind of medical toy, giving at best indications of disease which are more readily and certainly discoverable by other means. It may be true, as Dr. Holden asserts, that the disappointment which has arisen from its use is attributable to faults in its construction, which have been overcome by the modification of the instrument described in this essay. We shall attempt—although it is a difficult task without diagrams—to give our readers some idea of the nature of the alterations which the author has made. The spring of his instrument, instead of pressing down upon the artery, as in Marcy's, partially surrounds it, and, as a consequence, the displacing, and not merely the lifting, power of the vessel is utilized. Thus with each pulsation a force is transmitted not only upwards, but in oblique directions, the preponderance being towards the side upon which the spring may be inclined. "Prolong," he says, "the pulse-spring, and shorten the distance between the point of attachment (the fulcrum) and the point of pressure, and this upward and oblique movement is evident to the eye. To amplify this, allow the free and distal end to be bent as an inclined plane on the curve of a circle; polish it to obviate friction; magnetize it, if desired, to add a repellent power to the power already evident, and allow it to impinge against another lever quite near its attached extremity, make this last flexible, and its distal end will move with regular, accurate sweep under the distensible power transmitted." The movement obtained by this means is from side to side, and in consequence the paper to receive the tracing may lie as in ordinary writing. To make the tracing, an ordinary pen is used, pivoted in such a manner that the paper, and not the delicate

lever, carries its weight. The amount of pressure upon the artery is regulated by making the attachment of the pulse-spring to the body of the instrument by means of a coil of watch-spring, whose tension should be controlled and measured on a dial at will, an amount of pressure being possible beyond any requirement, and reaching four, five, or six points. These are the principal parts of the instrument; the accessories are very much the same as in that of Marcy. The principal advantages claimed by Dr. Holden for his sphygmograph are its cheapness and its ready applicability. No fastenings are employed, and hence there is no interference with the venous circulation. Moreover, no preparation is necessary; not even in most instances the preliminary rolling-up of the sleeve. The instrument is held by the finger and thumb of the left hand, the paper introduced, the ink applied, and the watch-work started by the other hand.

This is certainly a great simplification of the instrument, and it may be the more regular manner in which the pressure is applied will render its tracings more reliable as evidences of disease. We are not, however, prepared to admit that it has reached such a degree of excellence and perfection as to agree with its inventor in thinking that the "sphygmographic record of an applicant for life-insurance would be the safest record he could present as a test for his condition." That it may be relied upon too much, one of the cases reported by him shows, where, in consequence of what was regarded as a normal tracing, a limb was amputated, in defiance of the rules of good surgery, for gangrene, before the line of separation had formed. In fact, in the two hundred and ninety illustrations which he gives the tracings vary materially, and those obtained from healthy persons differ in many instances so slightly from those obtained from the sick that the physician who intends to depend upon the sphygmograph to indicate to him the existence of disease or its nature will find it necessary, if he is not blessed with an unusual memory, to carry a chart with him in his visits to his patients.

The last part of the book is devoted to some very carefully-recorded experiments made by the author with gelseminum, aconite, cannabis indica, and the sulphate of quinia. The tracings of the sphygmograph enabled him to determine that gelseminum, while it reduces the frequency of the pulse, increases the arterial tension, and after a time produces impairment of the heart's action in consequence of a toxic influence upon the nervous system. Aconite, on the other hand, he has found to reduce the frequency of the heart's action without increasing arterial tension.

We have not sufficient space at our command to justify us in entering into fuller details of the contents of the book, some idea of which may be derived from the titles of some of the chapters; they are as follows: "Indications Afforded by the Pulse;" "Translation of Tracings;" "General Properties observable by the Sphygmograph;" "The Practical Application of the Sphygmograph," etc. Dr. Holden is inclined to ascribe the dicrotous wave to the fact that "during the most violent portion of the propulsive effort of the heart, the onward movement may be almost uniform throughout the calibre of any given remote artery,—as, for example, the radial; but as this diminishes, the slowing of the current must appear in the part of it nearest the coats of the vessel, according to a well-known philosophical law, the best exemplification of which is seen in a running stream. In a tube of small dimensions another principle is introduced,—viz., that known as capillary attraction. In both cases, however, the same thing is true: the central part of the current is the last to fail and cease. These two philosophical facts seem to explain in every particular the phenomena of dicro-

tism. Under all circumstances, except those of such rigidity of arterial coats as to resist slight impressions, the condition might be educated. Careful adjustment of the instrument shows this to be true." He supports his theory by the fact that the wave is increased whenever the arterial tissues are in a state of atonic relaxation, or whenever the amount of blood thrown into the aorta is small, an event usually accompanied by the former condition.

The book has the advantage of being well printed on very good paper, and will, we doubt not, be interesting to those who use the sphygmograph. J. H. H.

HAND-BOOK OF MEDICAL AND SURGICAL REFERENCE. By JOHN A. WYETH, M.D. New York, William Wood & Co., 1873.

THE PHYSICIAN'S DOSE- AND SYMPTOM-BOOK. By JOSEPH H. WYTHES, A.M., M.D. Eleventh Edition, Revised. Philadelphia, Lindsay & Blakiston, 1873.

These books are of the same grade and of similar character, affording excellent ready-made patches to cover the bare places of ignoramus who are reckless enough to trifle with human life,—pocket editions ostensibly of the science and art of healing, but, in reality, of the science and art of killing. Dr. Wyeth dedicates his book "To the Young Men of the Medical Profession of the United States who are ambitious to succeed." We would amend this to read, "To the Young Men of the Medical Profession of the United States who are so foolish as to believe that success can be achieved by carrying in the breast-pocket knowledge which ought to be in the head." In conclusion, we have a word to say to those who feel a need of such books as these: Let this need show you your ignorance, and demonstrate the necessity of further education in your profession. Let it warn you not to touch the holy things with sacrilegious hands; not to assume, unprepared, the solemn responsibilities of life and death; not to become, through ignorance, pestilences walking at noonday.

SELECTIONS.

WRITING on the action of chemical substances upon the teeth, Prof. J. Foster Flagg uses the following language (*Dental Cosmos*, April, 1874). As he has had a very large experience, and justly enjoys the reputation of being a close observer, great weight seems to us to attach to his words:

"I must at this time, however, direct particular attention to the decided difference which we find to exist between the ordinary chemical action of acids upon such salts and organic tissue as compose tooth-structure and that action which results in caries, for it seems to be no less than *entirely* different. Frequent and long-continued experimentation has failed, in almost every instance, to produce any result which could be considered as analogous to caries; and when, in isolated instances, teeth have been subjected to influences, either accidentally or designedly, which have proven adequate to the induction of a semblance of this disease, it has been found that either the concomitant of galvanism in some form might easily be indicated, or that microscopic research has proven the existence of such pathological conditions structurally as would indicate decided local predisposition to decay, if even the incipency of actual caries had not been announced by decided 'tubular consolidation.' This latter has been invariably found in the comparatively limited number of examinations of this condition which I have personally been able to make.

"It is somewhat curious, in connection with all the various published results of experiments as to the effect upon teeth of an extended list of so-called injurious articles, embracing the many acids which are in daily use, such as acetic, citric, tartaric, malic, lactic, etc., together with sugar, meats, etc., that we remark only the effects noted, day after day, of enamel so altered in appearance as to have lost its brilliancy, or at length so altered in structure as to be easily scraped away with the finger-nail, or again, of dentine and cementum so softened as to be cut or even bent, and yet no particular mention made of the fact that these results were so unlike caries in every particular as to cause astonishment at their universally allotted position in the books in chapters upon this disease.

"Further than this, I have found repeatedly the most beneficial effects produced by the administration of medicines which, used locally in the seemingly accepted method of experiment, would be disastrous in the extreme; for example, nitro-muriatic acid will be recognized as eminently destructive of tooth-tissue, and thus is almost always prescribed with caution in this direction, and with injunctions that it shall be taken through a glass tube lest it make the teeth 'decay.' I have yet to see the first case of dental caries which I could attribute to the use of any acid medicine, while I have again and again seen remarkably *prompt cessation of dental tenderness and tendency to caries*, resulting from local weakness of tooth-structure consequent upon long-continued biliary difficulty, from the administration of fifteen to twenty drops of nitro-muriatic acid daily.

"It has for many years been accepted by observant dental practitioners that teeth are injured, to a certain extent, by the long-continued use of acid medicines; but it has also been noticed that the injury is *general*, just as in the ordinary experiments with acids, that enamel suffers most of all dental tissues, that it loses its brilliancy and density of structure, and that the cases in which this occurs most markedly are usually those in which the precaution of the 'tube' has been faithfully relied upon.

"For this reason, I have taught that the 'tube' was unreliable for the purpose used, and that such injurious action as was liable to ensue from acid medicaments should be prevented by rinsing the mouth *thoroughly* immediately after swallowing the medicine, using for this purpose water to which had been added a few drops of solution of ammonia, or in which had been dissolved a small quantity of bicarbonate of soda.

"Solutions of alum, which are frequently prescribed for many kinds of sore mouth, are found to be injurious in a general way only; acting more or less severely, according to frequency and continuance of applications and strength of solutions; these roughen and soften the enamel, and necessarily accelerate the progress of decay in already-formed cavities, but never seem to cause decay of the teeth in the circumscribed and localized manner which pertains to dental caries."

GLEANINGS FROM OUR EXCHANGES.

WOUND OF THE RIGHT ILIUM (*Trans. of the Medical Society of Virginia*, 1873).—Dr. S. C. Gleaves reports the case of a stout, athletic man æt. 35, who was shot with a Colt's navy pistol, the ball taking effect near the middle portion of the ilium, two inches below the crest, passing downwards and inwards nearly in a line with the symphysis pubis, and fracturing the bone through the crest. Contrary to orders, on the following day he rode ten miles on horseback. In a week he had slight fever and

great pain; the wound suppurating a little. In three weeks he had high fever with violent pain, the wound having ceased to suppurate for several days. The probe passed easily for three inches, but then met with resistance; water-dressings, morphia, and mercurial purgatives were ordered. In two or three days he improved somewhat, but about three weeks later grew much worse again, became weak and emaciated with heavy night-sweats, chills, anorexia, and symptoms of pyæmia and speedy dissolution. Careful palpation gave evidence of fluid in the pelvic cavity. There was no discoloration or tenderness in either the perineal or inguinal region. It was then resolved to trephine the pelvis. Brandy being administered, the patient was placed on his left side, his legs slightly flexed, and chloroform was administered. An incision three and a half inches long was then made through the glutei, directly above the great sciatic notch, and the parts were carefully dissected to the bone. A trephine was applied, and its withdrawal was followed by a full flow of sanious pus, thick and offensive. A digital examination did not reveal the presence of the ball. After a pint and a half of pus was discharged, a compress was applied and brandy and morphia given. From this time for three months a pint of pus was discharged daily, the patient taking three times in the twenty-four hours fifteen drops of tincture of the chloride of iron and three grains of sulphate of quinia, and using in the same time a pint of brandy or rye whisky. He was confined to his bed for five months, losing thirteen gallons of pus, and drinking sixteen gallons of whisky and brandy. He finally recovered entirely.

CHLORAL HYDRATE AND CAMPHOR AS A LOCAL APPLICATION IN NEURALGIA.—It is stated that the intimate mixture of equal parts of chloral hydrate and camphor will produce a clear fluid which is of the greatest value as a local application in neuralgia. Mr. Lenox Browne relates (*Brit. Med. Journ.*, March 7, 1874) that he has employed it, and induced professional friends to do so, and that in every case it afforded great, and in some instantaneous, relief. "Its success does not appear," he says, "to be at all dependent on the nerve affected, it being equally efficacious in neuralgia of the sciatica as of the trigeminus. I have found it of the greatest service in neuralgia of the larynx, and in relieving spasmodic cough of a nervous or hysterical character." It is only necessary to paint the mixture lightly over the painful part, and to allow it to dry. It never blisters, though it may occasion a tingling sensation of the skin. He has found it also an excellent application for toothache.—*Medical News*.

A NEW METHOD FOR THE TRANSFUSION OF BLOOD (*New York Medical Record*, March 30, 1874).—Dr. Joseph W. Howe believes that the essential parts of the ordinary process of transfusion are open to several grave objections. The blood, being exposed for a length of time to atmospheric influences, is liable to receive deleterious ingredients. In the process of "defibrination" a quantity of red globules, the chief nutritive and stimulating element of the blood, are necessarily entangled in the meshes of the fibrin, and are removed with it. In cases where the hemorrhage has been great, the time spent in defibrinating may be of vital importance. The wounds in the veins being comparatively large, there is more or less danger of phlebitis or thrombosis. Dr. Howe has slightly modified Dieulafoy's aspirator, and has used it for the purpose of transfusion. He employs rubber tubing about half the size of that which ordinarily belongs to the aspirator, and small needles with curved points. When ready for use the aspirator is placed in a basin of warm water, and allowed to remain there from the beginning to the termination of

the operation. A healthy adult being selected, a broad roller bandage is tied around the arm above the elbow, the fore-arm partially flexed, and the hand made to grasp tightly a round piece of wood. When the superficial veins are thus fully distended, a needle is inserted obliquely from above downwards into the median basilic vein. The operator grasps the rubber tube between the thumb and forefinger, turns the stop-cock of the aspirator, and allows the blood to rush in and fill up the cylinder. By compressing the tube occasionally, the blood will not be drawn out of the vein more quickly than it enters. A vein in the patient's arm having in the mean time been exposed, the air is expelled from the tube on the opposite side of the aspirator by forcing a little blood through it, or by sucking out the air and afterwards compressing the tube between the thumb and forefinger so as to prevent its re-entrance. The needle is then inserted into the vein, and the healthy blood thrown from the aspirator into the circulation of the exsanguinated patient.

When the vein is empty, or so small as to prevent the introduction of the needle, a canula may be employed. To do this the vein must be isolated for about an inch, and two ligatures passed around it. The ends of the lower ligature are crossed over the vein, brought down around the arm, and tied. This will prevent bleeding when the vein is opened. The wall of the vein is next pinched up with a forceps, an opening made through it, and the canula inserted; the upper ligature is tied over it to keep it in place, and the blood is then injected as before. Dr. Howe details a case in which he has recently and successfully employed this method. He claims for it the following advantages:

- "1. It takes less time than any other.
- "2. The blood is transferred without exposing it to the air.
- "3. The nutritive elements of the blood are not diminished.
- "4. As the fluid is drawn into a vacuum, there is no danger of coagula forming.
- "5. The opening in the vein being a simple needle-puncture, there is less danger of phlebitis or thrombosis."

THE ELASTIC LIGATURE (*The Lancet*, March 21, 1874).—Mr. Henry Kettle reports the case of a lady, who during four years of married life had always suffered excessive pain during coitus. For eighteen months this pain had been almost intolerable, and all sexual intercourse had ceased. She was in a depressed, emaciated, and generally miserable condition. She had been treated for some time by a distinguished specialist for vaginismus, but had never obtained any relief. Upon examination there was found growing from the posterior fourchette, more upon the left side than the right, what appeared to be an exaggerated third nymphæ, in breadth about an inch, but much broader at its free extremity; in length an inch and a half; it was exquisitely sensitive, so that even walking produced great pain. A double elastic ligature was passed through the base of the growth, and was tied on either side. In three days the whole of it had separated, leaving two small granulating spots, which were completely healed in three or four days more.

The cure was complete and permanent.

EMBOLISM AFTER THE INJECTION OF PERCHLORIDE OF IRON (*The Lancet*, March 21, 1874).—Mr. James F. West reports the case of a child, æt. 9 months, affected with a small nævoid tumor in the right ala nasi near the lip. It had existed from birth, but was slowly growing, and beginning to involve the left ala. It was soft and compressible, and over its surface large and distended capillaries were seen in three or four spots, each as large as a pea. Deformity from the prominent situa-

tion of the tumor necessitated operative interference; and as it was considered that no mode of operation offered so good an opportunity for the prevention of an ugly cicatrix as the injection of solution of perchloride of iron, it was decided to use it, and, chloroform having been given, three drops were injected by a hypodermic syringe into the lowest part of the tumor. The child struggled and cried, but there was no other unfavorable symptom. Three more drops were then injected into the upper part of the tumor, and three at another highly vascular spot, when, on withdrawing the syringe, the child's face changed suddenly to a dusky hue, the hands and feet became blue, the pulse could not be felt, and the breathing seemed to be arrested; on raising the eyelids, the eyeballs were seen to be fixed and turned upwards and outwards, and the pupils were slightly dilated. Artificial respiration was at once commenced, and in twenty minutes natural respiratory movements commenced. For the next six hours he continued semi-comatose, with a very feeble pulse, dilated pupils, livid hands and feet, and the angle of the mouth on the right side somewhat drawn down. He then became somewhat warmer, with a better pulse, and less labored breathing, but still remained unconscious. He continued in this state for three days, when he died, with well-marked symptoms of hemiplegia.

At the post-mortem examination, the membranes of the brain were found slightly congested; the anterior portion of both lobes of the cerebrum, and also the inner surface of the brain as seen in the walls of the lateral ventricles, were reduced to a soft pulp, while the posterior part of the brain-substance was in a healthy state. A clot was seen stretching from the right internal carotid artery along the middle cerebral artery of the same side. The lungs were congested. The heart contained a small quantity of dark fluid blood. The liver, kidneys, and other viscera were normal.

The embolism in this case was undoubtedly produced by the injection of the perchloride of iron, which should therefore be rejected as a remedy for nævi on the face.

SCIATICA PROMPTLY CURED BY CROTON CHLORAL HYDRATE.—Dr. R. W. Falconer, of Bath, relates (*Brit. Med. Journ.*, February 28, 1874) the following case:

"A lady, æt. 50, of rheumatic diathesis, was suddenly seized with sciatica. The pain was most severe. Two grains of croton chloral hydrate, with enough extractum anthemidis to make a pill, were given. Half an hour after taking the pill, the pain had ceased; there was a very slight return afterwards. With the beneficial effect of the croton chloral hydrate, there was 'some confusion of head, and near objects appeared distant.' She had no pain the following day until the evening; then a sharp attack occurred. Half a pill was given at once, and in twenty-five minutes the pain was gone. She had 'slight confusion of head; no alteration of vision.' There has been no recurrence of sciatica since. The first attack occurred fourteen days ago."

AQUAPUNCTURE IN THE TREATMENT OF NEURALGIA.—Dr. Siredey has employed aquapuncture for the last three years, for the relief of sciatic, intercostal, and ilio-lumbar neuralgia, and has always found it to produce considerable relief, and sometimes a cure by a single application. The process of aquapuncture consists in forcibly projecting with a particular apparatus an extremely fine jet of water upon a point of the skin. This produces at the spot a small raised blister with a minute orifice at its summit, from which flows a fluid colorless or sometimes tinged with blood. After a few hours the blister falls, and the following day a small dark scab is found in its place.—*L'Union Méd.*, March 3, 1874, from *Bull. de Thérap.*—*Medical News*.

MISCELLANY.

MEDICAL SCHOOLS AND GRADUATES.—There are in the United States, according to Dr. Toner, 101 medical teaching bodies, classified as follows: regular medicine, 77—of which 16 teach pharmacy; 8 homœopathic, 8 dental, 6 eclectic, and 2 botanic.

The annual accession to the ranks of the medical profession through American colleges is: Doctors of medicine, 1698; *ad eundem* degrees, 79; honorary, 16; and 5776 matriculants attending college. He says, if the returns were complete from all colleges, it would probably reach 2000 graduates, and perhaps 6500 in attendance on lectures.

The whole number of the medical profession of the United States numbers 62,383.—*The Cincinnati Lancet and Observer*.

MEDICAL GRADUATES IN 1874.—University of Pennsylvania, 121; Jefferson Medical College, Philadelphia, 151; College of Physicians and Surgeons, New York, 84; Bellevue Hospital Medical College, 181; College of Physicians and Surgeons, Baltimore, 26; Medical College of Ohio, 87; Medical Department of the University of Louisville, 123; Cincinnati College of Medicine and Surgery, 22; Chicago Medical College, 44; College of Physicians and Surgeons of Syracuse, N.Y., 9; Medical College of the Pacific, 12; Medical Department of the University of California, 8.—*Medical News*.

MECHANICAL CONTRACTION OF THE UTERUS.—Sir James Simpson used to mention a custom among some savage tribes, where, on the approach of labor, a stake was driven into the ground, and a long rope attached to it; the distal end of this rope was wound around the patient's body, and she herself gradually turned round so as to be brought nearer to the stake as the labor progressed, thus insuring an efficient following-up of the uterus upon the descending child, thereby preventing post-partum hemorrhage.—*British Medical Journal*.

ACCORDING to the *Baltimore Sun*, the communal council of Vienna has adopted, by a large majority, a proposal to establish in the cemetery the necessary apparatus for burning the bodies, the use of which will be optional and open to all. The council of Grätz has passed a similar resolution.

IN the séance of February 14, 1874, of the Société de Biologie of Paris, a note was read from M. Philipeaux, describing the case of two axolotls (batrachians) which had long suffered from chronic ascites, and were cured by tapping and the injection of alcohol into the peritoneal cavity.

A pow-wow doctress in Nazareth, Pennsylvania, recently undertook to bleed a lady for an epileptic fit. Unfortunately, she opened an artery instead of a vein, and the patient died before assistance could be obtained.—*Atlanta Medical and Surgical Journal*.

INCIPIENT abortion is said to have been arrested promptly by chloral hydrate.

MR. JOSEPH P. REMINGTON has been elected to the Chair of the Theory and Practice of Pharmacy in the College of Pharmacy of this city, recently rendered vacant by the death of Prof. Procter.

M. BALBIANI has been appointed to the chair of Embryology in the College of France, rendered vacant by the death of M. Coste.

ERRATUM.—In No. 127 of the *Philadelphia Medical Times*, p. 422, line 32, second column, for 15° C. read 16° C.

THE *Gazette Médicale* of March 7 contains an elaborate paper by M. Poncet on cysticercus in the eyeball.

THE American Medical Association meets this year at Detroit, Michigan, on June 2.

NOTES AND QUERIES.

MULTIPLE IMPREGNATION.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The following occurrence has seemed to me worthy a place in your Notes and Queries: A black-and-tan slut in my possession was covered, a short time since, by a dog of her own species, and within two hours by a spaniel. In due course she gave birth to a litter of six pups. Four of these are pure black, with curly wool, and other marks that indicate a relationship with the spaniel. The remaining two are tan-marked, with smooth, sleek hair, and undoubtedly must acknowledge the black-and-tan dog as the author of their being.

Very respectfully,

OBSERVER.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 7, 1874, TO APRIL 13, 1874, INCLUSIVE.

HEAD, J. F., SURGEON.—Granted leave of absence for twenty days on Surgeon's Certificate of Disability. S. O. 65, Department of Dakota, April 3, 1874.

HEGER, ANTHONY, SURGEON.—In addition to his present duties, during absence of Surgeon Head, to perform duties of Medical Director of the Department. S. O. 65, c. s., Department of Dakota.

BAILY, J. C., SURGEON.—To report in person to the Commanding General, Department of the South, for assignment. S. O. 78, A. G. O., April 10, 1874.

BROWN, HARVEY E., ASSISTANT-SURGEON.—Granted leave of absence for thirty days, with permission to apply for an extension of thirty days. S. O. 52, Department of the Gulf, April 1, 1874.

MIDDLETON, P., ASSISTANT-SURGEON.—Relieved from duty in Department of the South, and to report in person to the Commanding General, Department of Texas, for assignment. S. O. 78, c. s., A. G. O.

DEWITT, CALVIN, ASSISTANT-SURGEON.—To report in person to the Commanding General, Department of the South, for assignment. S. O. 78, c. s., A. G. O.

GIRARD, A. C., ASSISTANT-SURGEON.—Granted leave of absence for four months, on Surgeon's Certificate of Disability, with permission to go beyond sea. S. O. 79, A. G. O., April 11, 1874.

POPE, B. F., ASSISTANT-SURGEON.—Relieved from duty in the Department of the South, and to report in person to the Commanding General, Department of Texas, for assignment. S. O. 78, c. s., A. G. O.

CAMPBELL, A. B., ASSISTANT-SURGEON.—Assigned to duty at Ringgold Barracks, Texas. S. O. 54, Department of Texas, March 30, 1874.

STEINMETZ, W. R., ASSISTANT-SURGEON.—Relieved from duty in Department of Texas, to proceed to Baltimore, Maryland, and, on arrival, to report by letter to the Surgeon-General. S. O. 78, c. s., A. G. O.

HARVEY, P. F., ASSISTANT-SURGEON.—Relieved from duty in Department of Texas, to proceed to Burlington, Iowa, and, on arrival, report by letter to the Surgeon-General. S. O. 78, c. s., A. G. O.

SATURDAY, APRIL 25, 1874.

ORIGINAL LECTURES.

REPORT OF TWO CLINICAL LECTURES ON THE RELATION OF RENAL DISEASE AND HEART-DISEASE.

BY JAMES TYSON, M.D.,

One of the Visiting Physicians and Pathologist to the Philadelphia Hospital.

Reported by LOUIS STARR, M.D.

II.—KIDNEY-DISEASE TO HEART-DISEASE.

GENTLEMEN,—You will remember that at the last lecture we were engaged in considering combined cardiac and renal disease, and that your attention was then directed to the more rarely-detected form of the combined affection,—that in which the primary lesion lay in the heart. I propose then, to-day, to take up the second part of the subject, and will first bring before you a case in which disease of the kidneys has led to alteration in the heart.

The patient has been under observation for several years, and presents the following history:

Samuel —, 27 years of age, a baker by occupation, was admitted to the Philadelphia Hospital on June 2, 1871. He had always been perfectly temperate in habits, and, although a hard-working man, rarely became over-fatigued, and never exposed himself unduly to atmospheric changes. He has a healthy family history, and enjoyed remarkably good health until the spring of 1871, when he noticed that he was obliged to rise several times every night to void his urine, and that he had attacks of palpitation of the heart, and shortness of breath after exertion. Notwithstanding the continuance of these symptoms, he was able to work until June 1, 1871, when, without apparent cause, his eyelids became puffy, his legs began to swell, and he became very much prostrated. After admission the oedema extended rapidly, and in a few days involved the thighs, scrotum, and lower part of the abdomen. There is no exact information as to the presence of blood in his urine, but it is known to have been high-colored, albuminous, and diminished in quantity, the amount passed ranging from 450 to 900 cubic centimetres (15 to 30 oz.) per diem.

Under appropriate treatment he gradually improved, and on August 15, 1871, when he first came under my observation, was able to walk about the ward, all trace of oedema and ascites having disappeared. The urine at this time was normal in quantity, light-colored, had a sp. gr. of 1015, and contained an amount of albumen equal to one-third of the bulk of fluid tested, while the microscope revealed epithelial and granular casts and a few free epithelial and compound granule-cells.

From this date the improvement was continuous, and on May 15, 1872, with the exception of being easily fatigued, he had regained his usual health. The urine was again examined, and found to present the following characters: in quantity normal; color pale yellow; reaction acid; sp. gr. 1020; slight deposit of uric acid; large flocculent deposit of mucus, in which granular casts, occasional hyaline casts, and, more rarely, casts containing the nuclei of epithelial cells, were observed; amount of albumen, one-fifth of bulk tested.

An ophthalmoscopic examination was made by Dr.

C. B. Nancrede, but no alteration was discovered in the retinae.

The patient remained in this condition, being employed as nurse in the hospital, until March 27, 1873, when he began to suffer from headache, pain in the lumbar region, and a tendency to pyrexia in the evening. On testing the urine, the albumen was found to be increased to one-fourth of the bulk, and the microscope revealed numerous epithelial and hyaline casts, together with casts containing small oil-globules and a few blood-casts; some free blood-corpuscles and crystals of uric acid and oxalate of lime were also observed; the blood-corpuscles, however, were not sufficiently abundant to affect the color of the urine. These symptoms increased rapidly in severity, and on April 4 there were severe headache, intense pain in the lumbar region, oedema of the legs, frequent pulse, and augmented surface-temperature, the latter rising towards evening as high as 103° Fahr. The urine was highly albuminous, and was now plainly bloody to the naked eye; it was much reduced in quantity, 480 cubic centimetres (16 oz.) only being passed in twenty-four hours. Dry cups were applied over the kidneys, ice-bladders placed on the head, and the patient ordered, in addition, steam-baths, free purgation, and small doses of nitrate of potash and tincture of digitalis. Under this treatment the symptoms began to abate, and on April 6 Basham's mixture was substituted for the other medication. On the 7th, however, traces of erysipelas appeared about a small scalp-wound which had been received nineteen days before, and gradually spread, involving the right side of the head and face. He slowly recovered from this attack, and on April 25 was able to be out of bed, the oedema of the legs having entirely disappeared. On inspecting the urine at this date it was found to have the following characters: quantity normal, sp. gr. 1024, color light yellow, reaction acid, quantity of albumen small, scarcely sufficient to fill the concavity of the test-tube; numerous epithelial, granular, and hyaline casts were detected by the microscope.

From this time up to the present he has been employed about the hospital, and has remained in good health, except that he has had palpitation and dyspnoea after unusual exertion.

On examining the chest, slight bulging of the præcordia is observed, the area of cardiac dulness is increased, and the apex-beat, which is situated two inches below and a short distance outside of the line of the left nipple, is strong and heaving. No valvular murmur can be detected.

His general health is good; he has no calls to urinate during the night, and if it were not for the occasional attacks of palpitation and dyspnoea he would consider himself a perfectly well man. But when the urine is tested with nitric acid and heat, a precipitate of albumen, equal to one-fifth of the bulk of fluid, is thrown down, and when examined by the microscope a few granular casts can be seen. The latter conditions show that the kidneys have undergone permanent alteration, while the palpitation and dyspnoea are but too certain evidences of commencing heart-failure.

In all cases of combined renal and cardiac disease, in order that there may be a proper foundation on which to base the treatment, it is essential to determine—1, which organ is primarily affected; and 2, the exact nature of the alteration. This can only be done by careful investigation of the clinical

history of each case as it presents itself; and although it is easy to solve the first portion of the problem, it is sometimes difficult, especially when the disease has originated in the kidneys, to discover the extent and character of the structural change.

The form of kidney-disease which most usually gives rise to secondary heart-lesion is chronic contraction, or cirrhosis. In this condition the whole of the kidney is wasted, but the cortical or secreting portion most markedly so. The organ is small, hard, and pale, the capsule adherent, and the Malpighian bodies smaller and less numerous than in health, while the small arteries are more prominent, due to thickening of their walls. When a section of the cortical portion is examined microscopically, the renal tubules are observed to be shrunken and devoid of epithelium, and the interstitial fibrous tissue situated between them is increased. The amount of this fibrous tissue is small in the normal kidney, and its increase, according to Johnson and Beale, depends upon rapid destruction of the tubular structure, and not upon inflammatory proliferation of the stroma itself, as stated by Virchow and others. The former authors also maintain that the so-called stroma does not exist in the young kidney, but that it is developed as portions of the secreting structure become useless and are converted into fibrous intertubular substance. That the elements of connective tissue are present in the normal kidney, I can attest from the constant presence of connective-tissue corpuscles which I have met in many examinations; but that this tissue is present in minimum amount, so that it contributes in no way to the bulk or to the formation of a so-called stroma for the organ, I am equally certain. It appears to me, therefore, that we must admit the possibility of an inflammatory increase of these elements, as we admit and often see their increase in interstitial inflammations of the lung where connective tissue is primarily present in small quantity, though more abundant than in the kidney. But while admitting this as one of the modes of origin of the increased amount of fibrillated tissue between the tubes in the contracted kidney, I also believe, with Johnson and Beale, that the atrophy of the tubules and the destruction of their cellular contents contribute as well to the increase.

Before proceeding to explain the manner in which such changes produce alteration in the heart, it will be well to consider briefly the peculiarities of the renal circulation as accurately determined by Virchow. After entering the kidney the renal artery divides into three sets of branches, of which one set, belonging to the middle and outer portion of the cortical substance, goes exclusively to form the *afferent* vessels, which, entering the Malpighian capsules, divide to form the capillaries of the glomeruli; these reunite to leave the Malpighian capsule as *efferent* vessels, after which they again break up into capillaries once more to reunite as renal veins. At the boundary between the cortical and pyramidal portions there is a sort of neutral ground on which there are arteries from which branches arise, some passing through the course described, except that the efferent vessels,

instead of becoming a second time capillary, send off long offshoots (*vasa recta*) down into the cortical and medullary substances, and others which act directly as nutrient vessels for the medullary substance. Finally, there is a third set of branches of the renal artery which do not go to form glomeruli at all, but whose function is simply the nutrition of the medullary substance.

The water is filtered out in the glomeruli by simple blood-pressure or *vis a tergo*, in connection with the resistance which the blood meets in the glomeruli and narrow efferent vessels. Even under normal conditions this pressure is considerable, the renal artery being short and of disproportionately large calibre. The water thus eliminated passes down the tubuli uriniferi, and in filtering from cell to cell becomes charged with the solids of the urine which are removed by the cells in the convoluted tubules from the thickened blood in the second capillary network,—partly (inorganic principles) by simple osmosis, and partly (organic constituents) by a real act of secretion. Any increase in this pressure would be followed by an increase in the bulk of fluid removed: thus, if the abdominal aorta were tied below the origin of the renal arteries, the arterial tension would be increased and the amount of water greatly augmented, but there would be no albumen or casts. If, on the contrary, a ligature were placed around one of the renal veins, the venous side of the renal circulation would become turgid, while the engorgement could not extend through the narrow efferent vessels into the glomeruli, and there would be *no* increase in arterial tension. Under these circumstances the bulk of the urine is diminished, and it is found to contain albumen and casts. Now, it is plain that increased tension from arteriole spasm, and venous congestion from heart-failure, differ merely in degree from ligature of the aorta on the one hand, and ligature of a renal vein on the other.

In cirrhosis, a certain portion of each kidney is destroyed for all functional purposes, the balance between the products of metamorphosis and the power of elimination is disturbed, and the blood becomes poisoned. This condition of the blood, as first suggested by Ludwig, Traube, and others and confirmed by Johnson, produces spasm of the arterioles not only in the kidneys, but also in the tissues generally, the effort being, as it were, to cut off the access of impure blood. So far as it goes, this spasm is conservative, as it prevents further tissue-waste until the blood is purified and relaxation takes place; but, when frequently repeated, as its natural result there occurs hypertrophy of the muscular walls of the arteriole. But this constant obstruction to the circulation incites increased action on the part of the heart to overcome it, and soon leads to hypertrophy of the left ventricle. The whole arterial system is now subjected to a great strain, between the hypertrophied heart at one extremity and the contracted arterioles at the other, the two reacting upon each other. In the course of time slow inflammatory action is set up in the tunica intima, which, later, extends to the outer coats, and they become atheromatous, weakened, and

liable to dilatation. This condition once induced, if there should be from any cause suddenly increased pressure there is danger of rupture of the brittle arterial walls; and it is for this reason that such cases are often terminated by apoplexy. When this does not take place, the heart gradually undergoes fatty degeneration and subsequent dilatation, and the patient may die either from cardiac failure, or, if the lesion of the kidneys has advanced more rapidly, from uræmic poisoning.

Although all the changes which occur during the progress of the disease are in a measure conservative, allowing temporary approximation to a state of health, and enabling the system to support more easily the intercurrent affections arising through an impoverished blood, they nevertheless gradually impair the integrity of both organs, until they reach a point where life is no longer possible.

Fatty and amyloid degeneration, or indeed any affection of the kidneys, if of sufficient duration, may give rise to hypertrophy or dilatation of the heart, but less frequently than cirrhosis of the kidney, and to a less extent.

Besides the symptoms already mentioned in detailing the clinical history of the case before you, there are a number of others connected with inflammation of the stomach, intestines, and bronchi, which often occur during the course of the disease, and which are in themselves characteristic of it. The chief of these are vomiting, diarrhœa, and obstinate "winter-cough." Such events must also be regarded as in a measure conservative, for in nearly every instance they are the means of eliminating from the blood those waste products which can no longer be carried off by the proper emunctories. The same may be said of the skin-eruptions, and of the deposits of the uric-acid salts about the joints of the fingers and toes, both of which are often complications of combined heart- and kidney-disease. The various organs are, therefore, converted for the time being into supplemental kidneys.

Ophthalmoscopic examination alone is at times sufficient to justify a positive diagnosis as to the existence of renal disease. The appearances usually observed are white stellate spots on the retina, a swollen condition of the retinal vessels, and, in some cases, a form of uræmic cataract.

In conclusion, I desire to show you a set of specimens which strikingly illustrate the foregoing remarks, consisting of the *hypertrophied heart* and *two contracted kidneys*. They were derived from—

D. H., æt. 63, a native of Ireland, who entered the house on the 28th of January, 1874, completely unconscious. He is said to have been feeling badly for some days, in the out-wards or almshouse department, but tried to conceal his condition to avoid coming to the hospital. He was suddenly seized with convulsions on the morning of the 28th, and was brought to the wards at half-past 10 o'clock A.M.

When Dr. Guiteras, the resident physician, saw him, his respirations were 28 a minute, deep, and the regularity of their rhythm was only interrupted every five or eight minutes by convulsions which began with twitchings of the left side of the face, and extended all over the left side of the body, shaking the bed under him, and at times also involving the right lower extremity. The

respirations during the fit became jerking, his face purplish, and he foamed at the mouth. There was no œdema, no effusion into chest or abdomen. A full inspiratory murmur was heard over anterior of lungs. The pupils were normal, and responded to changes of light. He could not swallow. *His urine was examined, and found to contain about one-half of its bulk of albumen.* He then received a hypodermic injection of one-fourth of a grain of morphine, a few minutes after which he had his last convulsion. After this his coma continued. His bowels could not be opened by croton oil. Two more hypodermic injections of one-fourth of a grain of morphine were given, with the apparent effect of slowing his respirations down to 18 a minute, but they continued stertorous. His pulse, which before the first hypodermic had been frequent and not weak, became very hard and bounding, coming down from above 110 a minute to 100. At midnight tracheal râles began to be heard, and between 7 and 8 o'clock A.M. of the 29th he died, without any other change in his symptoms.

The urine for examination was drawn with a catheter. Not more than four fluidounces were found in the bladder. No more urine was passed, because the bladder was found empty on post-mortem examination.

No microscopic examination of the urine was made.

I need hardly say that the symptoms for twenty-four hours before death were those of uræmia, a frequent cause of death in this most insidious form of renal disease,—contracted kidney.

But let us study the specimens before us. The kidneys are very small, not more than half as large as in health. They contain each fifteen to twenty superficial cysts, from a line to three lines in diameter, filled with transparent fluid, and each kidney contained one larger cyst which held a fluidrachm of the same fluid. Further, the cortical or convoluted portion of the organ is greatly diminished in area.

Now, these are the grosser characters of the cirrhotic kidney. But I also examined the organs microscopically, with a view particularly to studying the condition of the arterioles. I had no difficulty in demonstrating the condition referred to. The walls of the arterioles, which are brought out with great distinctness by means of acetic acid, are seen to be twice and even three times as thick as in health, exhibiting quite the relative difference shown in the drawing on the board from Dr. Johnson's little book, of which the original was made from actual specimens. I have no time in this lecture to explain, or even describe, the other minute changes in the kidney, but will leave that to lectures more directly bearing upon the different forms of Bright's disease. Our present object is more particularly to illustrate the relation between the heart-affection and kidney-affection. There is one other appearance, however, to which I cannot refrain from alluding; and that is the appearance of concentric layers of connective tissue about the Malpighian bodies, which is here peculiarly distinct: so distinct and abundant is the fibrillation, so large and well-defined are the spindle-shaped connective-tissue corpuscles, that I cannot but think it affords evidence of the activity of the elements of connective tissue already referred to as sparsely present in the kidney, in the adventitia of the blood-vessels, if nowhere else, and which must be admitted as one of the sources

of the increased amount of fibrillated tissue present in this form of renal disease, but not the exclusive one.

Of equal interest in this connection is the condition of the heart. We may truthfully say it is enormously thickened. It weighs twenty ounces,* and the muscular walls of the left ventricle are twice as thick as they usually are in a healthy organ, while the valves are practically normal. There may be a slight degree of thickening of the mitral leaflets, but the valve is physiologically sufficient, and the condition resolves itself into one of pure hypertrophy of the left ventricle, which we believe to be due to the extraordinary efforts of the heart to overcome the resistance presented by the renal and general systemic arterioles through their hypertrophied muscular coat.

ORIGINAL COMMUNICATIONS.

ATOMIZATION OF BELLADONNA IN THE TREATMENT OF WHOOPING-COUGH.

BY JOHN R. HAYNES, M.D.

DURING the wide-spread epidemic of pertussis which occurred in the winter of 1872-3, my brother, Dr. Francis L. Haynes, intrusted to my care most of his cases of that disease, with the proviso that I should use belladonna by the atomizer, in treating them.

I recorded the cases treated in this manner, and they seem of sufficient interest to merit publication.

Case I.—Lizzie M., aged twenty-eight months; coughing began October 7, 1872, and on the 12th slight whooping was noticed. The whooping increased in severity, and the paroxysms became more and more frequent until treatment was commenced (Oct. 24), when they occurred at intervals of half an hour; moist râles were heard over the entire chest. The violence of the paroxysms was shown by the presence of spots of effused blood under the left conjunctiva.

The treatment consisted in the administration of one ounce of the following mixture by the steam atomizer:

℞ Ext. belladon., ʒiiss;
Ammon. bromid., gr. lxxx;
Potassii bromid., gr. xl;
Aq. dest., fʒiv.—M.

This process was repeated nearly every day until Nov. 5, making ten atomizations in all.

The following schedule shows the rapidity with which the patient improved.

Date.	No. of paroxysms in 24 hours.		Remarks.
October	24	40	Atomization commenced.
"	25	20	Atomization.
"	26	7	"
"	27	5	Atomization omitted.
"	28	6	"
"	29	5	Atomization.
"	30	6	"
"	31	4	"
November	1	4	Atomization; no whooping.
"	2	3	"
"	3	3	"
"	4	3	"

* Normal weight, ten ounces.

As may be observed, after the sixth atomization the whooping ceased, though rare paroxysms of coughing still occurred. There was no return of the whooping, and the coughing became less and less harassing, and after two weeks more ceased entirely.

Case II.—Benjamin L., aged twelve weeks; coughing commenced September 20, 1872; on the 27th whooping was noticed. Treatment was commenced on October 14. At that time, the child, though previously healthy, was emaciated and anæmic; numerous moist râles were heard over the chest, and the abundant secretion interfered so much with respiration as to cause serious alarm. Several convulsions had occurred since the onset of the disease. The paroxysms occurred at intervals of about one hour, and were very violent and long-continued.

At first but two drachms of the above-mentioned mixture were used; on the 16th the quantity was increased to half an ounce, and on the 17th to an ounce. Eight atomizations were used in all.

Date.	No. of paroxysms in 24 hours.		Remarks.
October 14	24		Atomization.
" 15	16		"
" 17	12		"
" 18	12		Atomization; no whooping.
" 20	10		"
" 21	8		"
" 23	5		"
" 26	3		"

During the treatment the child's general health improved immensely; when it was discontinued a slight cough was left, which lasted for about a fortnight longer.

In this case it is believed that timely treatment saved the child's life.

Case III.—Laura S., aged fifteen months, came under my charge February 20, 1873, having had whooping-cough for twelve weeks. During the last four weeks the cough has been very severe, and is not improving in the least.

A simple solution of ext. belladonna, of the strength of seven grains to the ounce, which was rapidly increased to fifteen grains, was administered.

Date.	No. of paroxysms in 24 hours.		Remarks.
February 20	44		Atomization.
" 21	30		"
" 28	8		"
March 1	5		"
" 4	10		"
" 6	7		Atomization; no whooping.

The subsequent history of this case was the same as that of Case II.

Remarks.—I have preserved the notes of eight additional cases treated in the same manner. Belladonna alone was used in all the cases except two, for it soon became apparent that this was the only efficient ingredient of the mixture at first employed. The strength of the solution varied from four to twenty-three grains to the ounce of water, which was the quantity generally used.

The satisfactory results related above were obtained in all the cases except one, in which no benefit whatever resulted, the disease pursuing its natural course. In one case treatment was commenced on the day after whooping became apparent, and with the effect of entirely preventing its return, although some paroxysmal cough remained for a month. Indeed, it was discovered that after

the spasmodic element of the disease had been eliminated it was useless to prolong the treatment, for the inhalations of belladonna had no influence on the subsequent cough. This, however, was of little moment, since after the whoop had disappeared the patient experienced but very slight annoyance from the remaining symptoms.

In nearly every instance atomization was followed by the appearance of the constitutional effects of belladonna,—dilatation of the pupils, dryness of the throat, and redness of the skin; slight delirium sometimes occurred. In one case where an unusually large quantity of the mixture was employed, the patient—a girl aged seven years—continued delirious for eight hours. If some of these effects did not follow the inhalation, it produced little or no benefit.

Almost always the inhalations would be followed by sleep, but exceptionally prolonged wakefulness would result. Thus, one anxious mother begged me to visit her child in the evenings, since it always slept so well after being “steamed,” while another complained that if I came in the evening the baby remained awake all night.

To compare the effects of belladonna when administered by inhalation and by the stomach, I treated two cases by the latter method.

Case I.—November 28, 1872; Mary A., aged 4 years, has coughed for two weeks and whooped for last five days; at present she has about twenty-four paroxysms daily. Ordered ten drops tinct. belladonna four times a day.

December 1.—No improvement. Ordered fifteen drops four times daily, and twenty drops at night.

December 2.—Slight reddening of skin and dilatation of pupils followed each dose yesterday. The last dose produced mild delirium, which lasted all night. Whooped twelve times during last twenty-four hours. Continue taking fifteen drops four times a day.

December 3.—Whooped four times during last twenty-four hours. Slight delirium for half an hour last night, after which she slept well.

She sleeps for one or two hours after every dose. Increased dose to twenty drops four times a day.

December 6.—The belladonna keeps pupils widely dilated, and causes drowsiness after each dose. Whoops four times a day. Treatment discontinued. In three weeks the patient had entirely recovered.

Case II.—January 3, 1873.—Sarah H., aged sixteen months, has had whooping-cough for four weeks. At present about thirty paroxysms occur daily. Ordered eight drops tinct. belladonna four times daily.

January 4.—Each dose produces momentary delirium, dilatation of pupils, and intense reddening of skin. Sixteen paroxysms occurred during the last twenty-four hours. Continue treatment.

January 5.—Ten paroxysms during the last twenty-four hours. I then lost sight of the patient.

In conclusion, it seems that belladonna by the stomach does not influence whooping-cough so decidedly as when given by inhalation. But it is probable that the former method of administration will generally be preferred, on account of its greater convenience.

By either method belladonna is useless unless a sufficient quantity is given to produce some of its constitutional effects.

ANASARCA—REPORT OF THREE CASES.

BY H. E. WOODBURY, M.D.

IN the month of October, 1872, I was called to Miss L. R., æt. 14. Her condition was as follows: pulse 78, and tolerably strong; tongue covered with a soft whitish coat; great dyspnoea, and much pain in the region of the heart; decubitus on the right side; could not lie in any other position; circumference around the abdomen $37\frac{1}{2}$ inches; extremities œdematous, and increased one-half in size by the effusion; eyelids puffy and transparent; complexion exceedingly sallow; bowels torpid; urine scanty; in short, all the symptoms indicated a well-marked case of anasarca.

From her stepmother I gleaned the following history. About two or three months previous to my visit, she had an attack of bilious fever. Up to that time her health had been good. The chills were very persistent, but finally yielded to quinine and arsenic, which had been given in heroic doses. Soon after they were controlled, the anasarca began to appear. Three physicians had expressed the opinion that the case was a hopeless one, before I was called. Having faith in the efficacy of certain remedies, I was hopeful, but not over-sanguine as to my prognosis of the case.

My first proceeding was to examine the urine carefully. Finding neither albumen nor sugar, I concluded that the anasarca resulted from nephritis, the latter having been superinduced by the continued use of the arsenical preparations. As the anasarca produced by arsenic generally subsides when the use of the drug is suspended, and as my patient had not taken it for weeks, I could not comprehend why the effusion had not diminished. On the contrary, it had been constantly increasing, until the poor girl had become so miserable that she longed to find in death a messenger that should bring her final relief from her suffering.

Treatment.—There was a never-failing spring of clear water near the patient's home. She was directed to drink three or four pints or even more of this water every twenty-four hours, if possible. Her limbs and body were bandaged, as much pressure being made as she could comfortably bear. The following recipes were ordered:

R Elaterin. (Clutterbuck's), gr. i;
Pulv. aloes, gr. v;
Podophyllin., gr. ij;
Rosæ conserv., q. s.

M. et ft. pil. no. x.

Sig.—One pill, morning, noon, and night.

R Vin. colchici, fʒi;
Tinct. digitalis, fʒiij;
Potass. iodid., ʒi;
Syr. sarsap., fʒi;
Aq. puræ, fʒiss.

M.

Sig.—A small teaspoonful three times a day.

Result of Treatment.—During the first twenty-four hours there was an increase of the urinary secretion, and she had evacuations of a scybalous character. The next day the amount of urine and fecal matter passed was almost incredible. On the morning of the third day the tape showed a diminution in the circumference of the abdomen of more than three inches. She could lie on her back, and her dyspnoea and cardiac pain had disappeared. She expressed herself as follows: “I feel like a new person; I shall get well.” By the fifth day, on account of the rapid disappearance of the fluid, the bandages had to be tightened several times in twenty-four hours, and the doses were gradually diminished in quantity, or given less frequently. About the twelfth day the circumference of the abdo-

men was 25½ inches, and the patient, although very anæmic and greatly debilitated, was able to sit propped up in bed during a portion of the day.

Tinct. ferri chlor. was ordered, and she took it for about two weeks. Her recovery was complete, and she has experienced no return of the disease.

Case II.—Mrs. V., æt. about 45; married; full habit; weight about 170 pounds; called on me for professional advice, four years ago. She was suffering from endocervicitis. This yielded promptly to treatment, and a short time after she came to consult me relative to her condition, believing herself to be pregnant on account of the great increase in her size. She appeared like a woman in the sixth month of pregnancy, but could not be sure that she had ever felt any movements of the fœtus. Her lower extremities were swollen and œdematous to such an extent that she was obliged to send to New York for hose, being unable to procure any large enough here, and she could not wear the shoes she had been accustomed to wear.

Upon questioning her, I learned that some members of her family had died of dropsy,—a disease she greatly feared. She had suffered from habitual constipation. At times the urine was scanty. She complained of a pain in her back, headache, and depression of spirits. Pulse, 80; tongue somewhat coated; heart-sounds normal; temperament bilious. She suffered most from the distention in the evening. I desired to examine her urine; she declined to have this done, saying, "It was examined some years since, and found all right."

Treatment, and its results.—Bandages were applied to the limbs and abdomen. The patient was directed to drink freely of the purest water. The same recipes were ordered as in Case I., with this exception,—the elaterin was increased to gr. jss in recipe No. 1. In a very few days there was a marked improvement, and in two weeks from my first visit my ministrations ceased. Mrs. V., by following the directions I gave her, had no return of the disease for two years. A slight attack about two years ago, when she was on a visit at the North (the result probably of some imprudence on her part), yielded promptly to treatment. A few weeks ago (Jan. 20) she called on me, and expressed the opinion that her dropsy was returning. Her abdomen was much enlarged, her limbs œdematous, and her general appearance confirmed the suspicion that such was the case. The same course of treatment was commenced as on the former occasion, and at the present writing (Feb. 12) the lady is in the enjoyment of her usual health, only experiencing the inconvenience of a very slight swelling of the feet whenever she has stood or walked much during the day. I do not consider her exempt from relapses of the disease in the future, but believe that by the use of elastic stockings, and a careful regulation of the secretions, she may succeed in keeping herself comfortable for many years to come.

Case III.—Mrs. J., æt. about 60, sent for me February 16, 1874. She was suffering from excessive dyspnoea, and feared that she would "die of suffocation." Her pulse was 90, weak, and intermittent; tongue coated; abdomen greatly enlarged. Had suffered from fever, insomnia, anorexia, and constipation.

Auscultation revealed valvular (mitral) disease of the heart. She informed me that her heart had been affected for many years; of late the symptoms had become more aggravated. In her case the swelling was principally confined to the abdomen (ascites), pleural cavities (hydrothorax), and left arm and hand. For months she had been unable to take her accustomed exercise, on account of the discomfort any exertion caused.

Prognosis unfavorable.

Treatment.—The medicine ordered for this patient was the same as in Case I.; the doses at first being smaller, on account of her age. As no unpleasant results followed their administration, they were gradually increased, and carefully watched until their full effects were obtained. Pressure by bandages applied around the body. Pure water ordered to be taken freely.

Results of Treatment.—February 17. Patient passed urine more freely during the night, and her breathing is somewhat improved. Pulse 84, and stronger.

February 18.—Since my last visit she has had copious evacuations, and passed urine very freely. Says she is "a great deal better." Pulse 80, and more regular.

February 19.—Action of the medicine has been kept up. Abdomen is much diminished in size. Her breathing is painless and natural. Pulse 80. Suspend the pills; take the diuretic mixture morning and night.

February 20.—Omitted my visit to-day.

February 21.—Found her somewhat nauseated to-day, probably from taking oysters that were not fresh. Stopped the diuretic, and ordered cod-liver oil, ʒss three times a day.

February 23.—Patient is up a portion of each day, and feels very comfortable. Still wears the bandage, and takes a pill or a teaspoonful of the diuretic occasionally as her condition requires. Her appetite is improved, and she is gaining strength.

March 5.—Called on Mrs. J. to-day. She was engaged in writing when I entered, and looked as hearty and well as before her illness. She informed me that when she sent for me she never expected to feel so well as at present. In cases like hers, where the disease results from an organic derangement of the heart,—a condition we are unable to remove,—it is very satisfactory to be able to afford our patient such marked—even though it may prove but temporary—relief from suffering.

Our purpose in reporting these cases is to call the attention of the profession to two points in the treatment, the value of which we believe to have been greatly underrated in such cases,—viz., the value of pure water as a diuretic, and the value of pressure as a mechanical means for preventing infiltration of the tissues. We have used these in many other instances, and with results that have fully justified us in arriving at the conclusion that they should never be overlooked in the treatment of a case of ascites or anasarca.

WASHINGTON, D.C., March 7, 1874.

SEPTIC SYMPTOMS PRODUCED BY DECAYING SAUSAGE.

BY DR. J. BERENS.

THE following case is of such character as to seem worthy of a brief record:

Upon being called to see a female patient, æt. 30, and affected with nymphomania, I found her in bed with fever, prostration, and other well-marked symptoms of septicæmia, for which no apparent cause could be assigned. Close questioning, however, revealed the fact that, to satisfy her cravings, she had resorted to a piece of Bologna sausage, a part of which had broken off and remained within the cavity of the vagina. Putrefaction had evidently set in, followed by the result indicated above. All doubt was dispelled by the production of a vessel containing the offending piece, which had been discharged an hour previous. Although much disorganized, it retained sufficient semblance of its former self to render recognition certain.

Under the use of disinfectant vaginal washes, the woman soon recovered.

THE EUCALYPTUS.

BY A. L. FLINT, M.D., U.S.A.

DURING the past few years the *Eucalyptus globulus*, an Australian gum tree, has been successfully acclimated in Algeria, Southern France, Egypt, Cuba, and California. It is a fine-looking, fragrant evergreen, and belongs to the myrtle family. Its leaves are opposite, nearly sessile, ovate-lanceolate, faintly bluish underneath, and the trunk and branches of the young trees are similarly tinged: hence the common name, blue gum. It grows rapidly, and in its native country attains a gigantic size, rivalling the "big trees" of California. M. Gimbert, who has read a paper on the *Eucalyptus* to the French Academy of Sciences, says, "It absorbs ten times its weight of water from the soil, destroys miasmatic influence, and has the property of emitting antiseptic, camphorous effluvia."

The London *Medical Times and Gazette*, commenting on M. Gimbert's paper, remarks:

"We have no information as to whether this beneficent tree will grow in other than hot climates. We hope experiments will be made to determine this point."

Mr. V. F. B. Stanford, of Pix-house, Tinsbury, England, had already determined the matter, and wrote to that paper, Nov. 22, 1873, the following communication:

"As I have successfully reared from seeds two dozen of these trees, and as they are now growing well out-of-doors, I think some of your readers would like to know how I succeeded. I obtained the seed five years ago from South Australia, and forced it in a hot-house. In one year it was four feet high, and now, in its fifth year, it is growing rapidly in a sheltered position in the park, having attained a height of thirty feet. The first three years the tree must be taken under cover every winter, and the fourth and fifth year should be protected for several feet up with wisps of hay or straw. In-doors it should be kept in an orangery or very high greenhouse, with plenty of light and little water (?). I have sent specimens of my five-years-old tree to Milton Abbey, Dorsetshire, and to Donhead Rectory, Wilts, where, I believe, they also flourish."

The lowest temperature during the past two years in eighteen of the principal towns of England was 16°, at Sheffield. The gum trees, therefore, would no doubt do well, with a little care, on the east side of our Appalachian range, in about latitude 33°, where the magnolia is native, and, of course, at any point farther south. In California they grow quite into the foot-hills of the Sierras, where snow often falls.

The seeds of the blue gum are very small and black, somewhat resembling onion-seeds. The writer bought some two years ago while in San Francisco, and in April of last year planted them in boxes. In ten days several of the sprouts were up, and, in all, forty-five plants appeared. They thrived for a time, but absence caused them to be neglected. The San Francisco florists have eight or more species of *Eucalyptus*. The *Eucalyptus giganteus* (stringy-bark gum) is said to be a fine tree. *Eucalyptus paludosus* (swamp-gum) is planted in wet soils.

If any of the readers of the *Times*, particularly Southern medical men, wish to try, on a small scale, the experiment of raising these trees, they can easily do so at a nominal expense, say fifty or sixty cents only, for a package of seed. Mr. E. E. Moore, 425 Washington Street, San Francisco, or any other florist in that city, has the Australian seed. Eastern seedsmen may also have it.

FORT McPHERSON, NEBRASKA, March 20, 1874.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. H. C. WOOD, JR.

Reported by JOSEPH A. MCCAULEY, M.D., Resident Physician.

CASE OF CEREBRAL SARCOMA WITHOUT AFFECTION OF THE OPTIC DISK.

R. T., 50 years of age, female, born in New Jersey, was admitted into the medical wards from the out-wards January 30, 1874, for chronic rheumatism in the right shoulder and knee. She also complained of constant and severe pain in the head.

About one month after her admission, the following phenomena were first noticed. She would get up out of her bed, catching hold of everything, and upsetting them, seemingly unconscious of her movements. Directly after this she would invariably fall backwards upon the floor, lying on her back, foaming at the mouth, and unconscious, and offering all the phenomena of a fit of epilepsy.

When these would pass off, and she was questioned how she felt, she said she did not know what she was doing, that she had no consciousness of having got out of bed, and that before the attack she had an irresistible feeling as if she were all the time going backwards.

She had three of these well-marked attacks, but frequently had slight paroxysms with the same premonitory feelings, and loss of consciousness. She was at first put on large doses of iodide of potassium, and afterwards on bromide. Sometimes she would feel markedly relieved, and we would have hopes of her improvement, and then suddenly she would relapse. She also would sometimes be attacked with persistent vomiting, which, however, yielded to treatment. On Sunday, the day before she died, a careful examination by Profs. William Norris and H. C. Wood revealed that the optic disks were normal.

The day she died I was in the ward about ten or fifteen minutes before her death, when she was seemingly very comfortable. I went into the office to write some orders, when the assistant-nurse came and reported her as having one of those epileptic attacks. I immediately went down to the ward, but found her dead. There was at no time any paralysis present in this case.

At the post-mortem examination there was found a tumor, rather elongated in shape, one and a half inches long and one inch in diameter, attached by a pedicle to the cerebrum, resting in the olfactory groove, involving the pia mater and arachnoid, destroying the olfactory nerve, and softening the brain-substance around, but not disintegrating it much.

It was of pale pink color, rather irregular, formed of many small lobules, which were joined together into larger lobules by trabeculae of connective tissue, resembling much a salivary gland; consistence firm.

The cerebellum was found slightly congested and very much softened.

On microscopic examination of a section of the tumor, it was found to be a sarcoma, with spindle-shaped cells. The other organs of the body were healthy, with the exception of the liver and kidneys, which were congested.

TRANSLATIONS.

POISONING BY NITRO-BENZINE.—M. Limasset reports the following case in *L'Union Médicale*, February 7, 1874:

A man who had been suffering for some time from scabies was ordered a liniment containing nitro-benzine. Applying this in the evening, he retired, and awoke the following morning suffering from a slight headache. Finding it increasing, and being somewhat drowsy, he lay down and slept, but soon awoke with numbness of the fingers, ringing in the head, and vertigo. Attempting to walk, his movements were uncertain; he became more languid, and finally could not walk without assistance. At this time M. Limasset first saw him, and found him livid and cyanosed, his hands cold, finger-nails discolored, and head flexed upon his neck. He vomited, frequently, matters of a vinous red color. His person exhaled a strong odor of bitter almonds. The heart-sounds were healthy, saving a slight exaggeration of the bruit. The tongue, gums, and walls of the mouth and pharynx were all colored blue. The intellect continued unimpaired.

Fresh air was immediately admitted to the apartment, an emetic administered, and aromatic vinegar applied to the nostrils. Under the influence of these remedies the more threatening symptoms gradually disappeared. The breath and sputa remained odorless of bitter almonds, while the urine was pale, and quite free from smell.

Blood drawn forty-eight hours later had no abnormal odor; it was at first dark, but soon changed to vermilion red.

A week later the patient was quite well, save that a slight blue tint remained, and the sputa still gave out a faint odor of bitter almonds. In this case Dr. Limasset concludes that the nitro-benzine, whether or not it was changed into aniline in the blood, acted as a poison. In another case cited by him, when this substance was taken into the stomach the result was fatal. A. V. H.

RHEUMATISM IN CHILDREN.—M. Constant Picot has been at some pains to work up a subject which does not seem to have received hitherto the attention at the hands of writers on the diseases of children which its importance deserves. His observations, made chiefly at the Hospital for Sick Children in Paris, are published in a brochure (*Du Rhumatisme Aigu, et de ses diverses Manifestations chez les Enfants*), and seem to sustain facts which, though not in any way new, have not before appeared in a systematic and connected way. The book is very interesting, and, so far as is possible with its class, satisfactory; but we never finish reading a work on any branch of clinical medicine without a feeling of sympathy with the author, and thinking of the remark made by an old and wise man: "The human body is so wonderful that I fear you doctors will never really know much about it."

Some of the principal points of the work are summed up in a chapter of conclusions as follows:

1. Rheumatism is a somewhat common affection among children from the age of seven or eight years and upwards: it is very rare under five years.

2. The symptoms of articular rheumatism are in children generally less intense, and their duration is shorter, than among adults.

3. The cardiac complications of rheumatism are very frequent in children: indeed, they are almost the rule, and may occur even in subacute cases.

4. Rheumatic cardiac affections in children sometimes disappear without leaving a trace, but they may in other cases terminate in an organic affection of the heart which is rapidly fatal.

5. Pleurisy is not infrequent as a result of rheumatic pericarditis; it occupies the left side, but may become double.

6. Cerebral rheumatism occurs among children: it is frequently attended by clonic convulsions.

7. Chorea is often a manifestation of rheumatism; it follows, accompanies, or more rarely precedes the articular pains.

8. Rheumatic chorea very often but not always attends heart-trouble. Chorea and disease of the heart may be present at the same time in a child who has never manifested pains in the joints.

9. The most satisfactory theory of rheumatic chorea is that the disorders of motility are the result of the rheumatic action upon the nervous centres, and more particularly upon the cord and its coverings.

10. Muscular rheumatism is rare in childhood. Torticollis is often produced by a cervical arthritis.

11. *Rheumatism* in children is very often under hereditary influences.

12. That form called scarlatinal rheumatism is an affection analogous to ordinary rheumatism. Scarlatina is only the occasional cause of rheumatism.

13. Endocarditis recurring in scarlatinal rheumatism usually disappears without leaving permanent heart-lesions.

14. If we compare in a general way the acute rheumatism of childhood with that of adult life, we find that, whilst in young subjects it displays a lower degree of intensity, it has on the other hand a greater tendency to leave the articulations and invade internal organs. Visceral manifestations in rheumatism are more frequent among the young than among adults.

RESULT OF THE UNION OF MOTOR AND SENSORY NERVE-FIBRES.—M. Vulpian has made a series of experiments in uniting the peripheral end of a motor nerve (the hypoglossal) with the central end of a sensory (the lingual).

Complete union having been obtained, after a certain lapse of time the course of the lingual was laid bare, severed from its central connections, and irritated by electricity, etc. No movements of the tongue were produced, save in a single case, when incomplete isolation was suspected.

M. Vulpian concludes that either the greater number of the regenerated fibres on the peripheral side of the hypoglossal nerve do not immediately take on their normal relations with the primitive muscular fasciculi of the tongue, or else that these regenerated fibres are essentially but prolongations of the fibres belonging to the central end of the lingual nerve, and, like those, possess no aptitude for causing contraction of the lingual muscles. He considers the result of his experiments to be a decided refutation of the opinion of those physiologists who believe that sensory, motor, and sympathetic nerve-fibres possess one common property, —neurility; a property which, roused into activity, gives rise to different effects according to the central or peripheral connections of the nerve-fibres in which it comes into play.—*Gaz. Méd. de Paris*, Feb. 14, 1874.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 25, 1874.

EDITORIAL.

CREMATION.

AS our readers know, the proposition so actively supported, if not originated, by Sir Henry Thompson has given rise to a great deal of discussion, and it seems as though the ceremony of burning the dead might actually be introduced among us,—if, indeed, its friends do not kill it by their absurd methods of advocacy. The only question, it seems to us, is one of convenience and hygiene: the putting forward of economical reasons, as is done, belittles and makes ridiculous the whole subject. New York has now its cremation society, led by the immortal Bergh, and some of the speeches made at its organization offer fine illustrations of that method of advocacy which, even in the hands of Sir Henry Thompson, has proven so destructive to the project. Mr. E. B. Schnabel said, *inter alia*:

“Consider the wastage of 1,400,000,000 of people [the number of the annual dead] every year. You take away the fructifying element essential to the earth. Look at the mode of cultivating the soil in Virginia. There are counties on the James River that year in and year out are cultivated without giving fructifying elements back to the soil, until absolutely destroyed and thrown into commons.

“The thing most essential for the growth of vegetables is carbonic acid. It is a grand mistake to urn your ashes. Let them be scattered over the fields. The baby born weighs two pounds: this body weighs two hundred and fifty pounds. Where did I get it? By eating wheat and fruits and meat. If I bury my body beyond fructification, I am a thief. You can appeal

to the fine fat fellows, the gourmands. Tell them, if I die, my gases are given to the earth, my ashes are scattered over the earth, and nourish the seeds and plants. The ox eats the plants, and men eat the ox, and those very elements come back and live again. Physical existence must be pleasing to such persons.”

So, then, we are to burn our fathers and our grandfathers in order that strawberries may be sweeter, and cream richer; that wheat may be cheaper, and beef more abundant.

O fools and slow of heart, to think men are to be moved by such arguments as these! Why, New York City, alone, yearly pours from its sewers into the abyss of the Atlantic a vastly richer freight of vegetable possibilities than the smoking fires of a world's cremation could produce.

Again, when a man is buried, what becomes of him? Just as surely must the elements out of which he is made return to the soil as though his ashes were preserved in a sepulchral urn. If the hygienic necessities of modern civilization demand it, by all means let us have cremation. But if a pretentious economy is all that is offered, far more precious are the hallowed associations of the past, and the sacred memories of our buried dead.

PRESCRIPTION-WRITING.

ALTHOUGH it is of very much more importance what is put in a prescription than how it is written, yet the reputation of a physician as an educated man, if not as a practitioner, is, we think, greatly affected by the manner as well as by the matter of the doing. We have not, however, taken our editorial goose-quill in hand for the purpose of inditing a homily upon “prescription-writing:” we merely want to call attention to an error which seems at present universal; at least we have not seen a prescription in the last two years correctly written, and we have looked at a good many hundred of those of the most prominent physicians. As every one knows, chemical nomenclature has gone into the line of the acrobat, and in the last few years somersaulted most actively. As no one seems to know, the United States Pharmacopœia has, to a certain extent, followed these changes. It is now no longer correct to write *magnesiæ sulphas*, or *sodæ sulphas*, or *potassæ nitras*. The name of the metal itself is employed, not that of its oxide. Thus, the substances mentioned should be respectively called *magnesiî sulphas*, *sodiî sulphas*, *potassiî sulphas*. Again, neither *ammonii* nor *ammoniæ murias* is officinal, but *ammonii chloridum*. *Verbum sat sap.* Look at your Pharmacopœias.

CREDULITY.

ACCORDING to the foreign correspondent of the *Medical Investigator*, Dr. Horn, a German homœopath, has discovered the veritable *corpus delicti* of cholera. It seems that a person who has swallowed similia similibus curantur in therapeutics has in the operation so stretched his intellectual throat that a boa-constrictor would hide his head for shame and envy at the human capacity for swallowing.

The cause is as follows:

"The cholera originates from two factors or agents acting upon the human organism in a very noxious manner.

"1. From a reduction of the *magnetism of the earth*, which penetrates every individual; and

"2. From the action of a *positive* electric current of the earth, of *volcanic* origin, touching our city for some time already, and rendering our atmosphere *negative*-electric by influence.

"From the effects of the *latter* electricity, an increased quantity of certain *carbo-nitrogenous* compounds arises in the blood, whereby the lower forms of cholera are produced, as those compounds or bodies affect the blood to some extent, while the malignant and, as yet, incurable forms of cholera originate by a poisoning of *prussic acid* and *hydrocyanic acid* compounds, which, under certain conditions, are developed out of the *carbo-nitrogenous* bodies."

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The leading article in the *American Journal of the Medical Sciences* for April is a study of the functions of the human brain, by Prof. Bartholow.

Mary Rafferty, æt. 30, Irish, was admitted to the Good Samaritan Hospital,—Cincinnati, we presume,—and there suffered certain things, now to be told, at the hands of a good Samaritan. Had Mary been other than "feeble-minded," perhaps she might have been in doubt as to whether the hospital in which these things were allowed was not a misnomer, and whether some other of the earlier-mentioned personages of that curious parable might not have been more rightly honored in the naming of it.

The experiments made on the vile corpus of Mrs. Rafferty seem to have been done without her assent. First, the dura mater and brain were mechanically irritated. As to results, we shall say little or nothing. Second, two needles were carried into the dura mater, and an induction-current passed through them. Third, an insulated needle was passed *into* the left posterior lobe of the brain, etc. A form of convulsion was brought on by the passing of an electric current in this case from the dura mater to the needle in the brain. Unpleasant sense of tingling occurred, but, "notwith-

standing the very evident pain from which she suffered, she smiled as if much amused." A less than little knowledge was good for her comfort. But see what was next done to her. The needle was passed into the right posterior lobe of the brain, which, it seems, caused acute pain in the neck. The current was made more powerful than in the last case, when she "exhibited great distress," and proceeded to have a well-organized fit of epilepsy, followed by coma. Suppose, Dr. B., that Mrs. R.'s tortured body had been meanwhile deserted by its tenant,—life,—would this have been any form of manslaughter? Yet some of us have seen folks die in a fit.

Two days later it was meant to examine the posterior lobes by galvanism; but, strange to say, her lips were blue, she was pale, depressed, and had evident difficulty in locomotion. So the experiment was given up. Also, then and there, she had a slight fit, and also one next day, followed by palsy. It is not stated that she died, but in the next paragraph we have the autopsy described. Yet, after the facts above given, an ante-mortem section would have been in order, and might have been made, and called by courtesy an autopsy.

"*Results of cadaveric section.*—The needle-tracks we learn could be distinctly traced. They entered the brain *one and a half inches!*"

"The needle-tracks were marked by lines of diffu-
lent cerebral substance."

Dr. B. thinks needles cannot be thus used in the brain without mischief. The fatal result was due, he thinks, to the extension of the epitheliomatous ulceration to the sinus; to consequent thrombus, arachnitis, etc. Let us hope that there was no other factor in the grim equation of this poor woman's death. No man on earth can settle this question. There should never have arisen for settlement so ghastly a query. No craving for knowledge, no need for it, can be called upon to justify an act which subjects a poor feeble-minded hospital patient to experiments which cause convulsions and leave the brain in a state of local softening.

A HOSPITAL PATIENT.

NOT OF THE GOOD SAMARITAN HOSPITAL.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held Wednesday, January 28, 1874, at 8 o'clock P.M.

DR. I. E. ESHLEMAN, VICE-PRESIDENT, in the chair.

DR. W. B. ATKINSON introduced Mr. MORTON, who exhibited a specimen of Dr. Grosvenor's improved belladonna plaster, which he said was of official strength.

RAPID DILATATION OF THE UTERUS.

DR. WILLIAM GOODELL made some remarks upon the rapid dilatation of the cervical canal, and exhibited the dilators of Drs. Wilson, Atlee, and Molesworth. He gave the history of several cases of dysmenorrhœa, ante-
flexion and retroflexion, in which he had obtained

marked relief by this method. When the woman is married he prefers to introduce the dilator by means of a speculum; but when unmarried, without. In tortuous and contracted cervical canals he formerly had been days, and even weeks, in gaining the cavity of the uterus by relays of the smallest of sponge-tents. But now he would undertake to tunnel out the most contracted canal in less than fifteen minutes' time. The method he recommended is as follows. The smallest of the dilators is introduced as far as it will go, and then opened. After gently stretching that portion of the canal it occupies, the strictured portion just above so yields that, when the instrument is closed, it can be made to pass up higher. Thus, by similar repetitions, little by little, the dilator tunnels its way into the uterine cavity. When this is reached, the blades are withdrawn for about half an inch, viz., far enough to keep their tips clear of the fundus, and then their handles are brought firmly together. In bad cases of metrorrhagia arising from fibroid tumors, he had successfully made use of an intra-uterine injection of the undiluted tincture of iodine, and had obtained a free channel for the escape of the fluid, by first stretching open the canal by the dilator, and then introducing the slender nozzle of the syringe between the open blades. He had also found this instrument to be very efficient in preparing the cervical canal for the admission of a very large tent or a batch of tents, by which the requisite amount of dilatation could be effected by but one operation. This he considered a step in the right direction, for it is usually not the first tent or batch of tents introduced at the first visit that do the mischief, but those introduced on the second or third visit. The pressure of the first tent produces a congestion or traumatic irritation of the cervix. Its removal abrades the mucous surface more or less, and by this raw and now actively absorbent surface are taken into the system the putrid discharges generated and retained by subsequent tents.

Dr. I. E. ESHLEMAN requested Dr. Goodell to go further in his excellent remarks, and explain to the Society how, according to his experience, the cervix might best be prepared for the introduction of the dilators, when found so contracted as to resist the introduction of the most delicate silver probe.

Dr. GOODELL replied that when the os externum is too contracted to admit the tip of the dilator, he first bores open with the pointed blade of his scissors.

Dr. T. M. DRYSDALE said he agreed to most that Dr. Goodell had stated in reference to the use of the uterine dilator, and, like him, regarded it as a most valuable instrument. As regards the uterotome, he did not consider it a dangerous instrument when properly employed. He had operated freely with it for many years, and had yet to see an unpleasant symptom from its use. He had been surprised to find so little said about the dilator in works on uterine diseases or in the journals. He had recently seen an article on the subject, which was published in a January number of the *Medical and Surgical Reporter*, by Dr. Goodell. He had read that paper with much pleasure, but wished to correct an error in it. In the article referred to, Dr. Goodell, after describing the method of using the dilator and its various applications, says, "It is but just to add that to Dr. Ellwood Wilson is the profession of this city indebted for this method of rapid dilatation, a method which bids fair to revolutionize the treatment of many uterine disorders" (*Medical and Surgical Reporter*, January 17, 1874, p. 49). This was a mistake. To Dr. W. L. Atlee was due the credit of introducing this method of treatment. The uterine dilator was invented by Dr. Washington L. Atlee, of this city, his first instrument being made under his instruction by Mr. Liemann, of New York, in 1861. The instrument became pop-

ular with the profession of that city under the name of Atlee's dilator, and Liemann published a wood-cut of it in his catalogue under the same name. He also wrote to Dr. Atlee asking him to furnish a description of the instrument and its use, for publication in one of the New York journals. Mr. Gemrig, of this city, having had repeated demands for the dilator, called on Dr. Atlee for his instrument, and from this model made others, which are sold by him and described in his catalogue as Atlee's uterine dilator. The instrument and one of its uses are referred to in the address on obstetrics, by Dr. W. L. Atlee, published in the Transactions of the State Medical Society of Pennsylvania, 1872, p. 61, but it is more particularly described in an article on "The Uterine Dilator," by Dr. W. L. Atlee, in the *American Journal of the Medical Sciences* for April, 1871, p. 395. He had used this instrument since 1861 as a dilator in cases similar to those described by Dr. Goodell, and knew that Dr. Atlee had also used it for the same purpose. He had also applied it after section with the uterotome, to keep the cervical canal patulous. Its name, however, implies its use.

He had made trial of Dr. Molesworth's instrument, but had been disappointed in the use of the smaller tube. The first time he filled the smallest one the inner fibres of the rubber ruptured, causing a large swelling or tumor to form on its side. Another tube supplied by Dr. Molesworth ruptured in a similar manner. Since then, he has had two others sent to him, but has not tested them. He would fear to use the tubes without first trying them. In reference to Wright's pessary, an objection to its use was that it became corroded when retained for any length of time in the uterus. He had used it, however, successfully in retroflexion.

REVIEWS AND BOOK NOTICES.

A MANUAL OF MIDWIFERY, INCLUDING THE PATHOLOGY OF PREGNANCY AND THE PUERPERAL STATE. By Dr. KARL SCHROEDER. Translated into English, from the Third German Edition, by CHARLES H. CARTER, B.A., M.D., etc. New York, D. Appleton & Co., 1873.

A work like that before us stands almost alone. Its style is profound, minute,—in fact, German. There is no elaboration; each short sentence contains the germ which, in a diffuse English or American author, would spread over a paragraph or page, and then serve by its very mass to conceal the truth it professed to elucidate.

To minds of a certain class, to the slaves of method, who find their solace in always knowing what and where everything is, on the shelves of whose memories every fact ever met with is always placed in its appropriate spot, ready for use, a book like this is a joy. Like the various heads of an old-time New England discourse, Schroeder has arranged everything. Everything that can happen, everything one can do or see in the lying-in room, is provided for in his scheme, under its appropriate heading. To some, the restraint of such a system is galling; yet the patient study of the manner, to say nothing of the matter, of such a work, would make many an apt observer of far more value to himself and the world. The book cannot be skimmed; it must be studied. Its sentences need often, so we have found it, to be read and read again, before their exact import is fully understood. Nor is it a book in which the undergraduate would revel, as an easy method of learning midwifery. Compact, dry, scolding illustration, it is a book for the true student, for him whose school is over only when his days are done.

The work is divided into eight parts, the parts into chapters. For want of space, we will confine ourselves to Part VI. almost entirely. As an illustration of his method, we give the scheme for the pathology of parturition:

"1. Too feeble action of the expelling forces. 2. Too great obstacles. 3. Dangerous accidents, which do not interfere with the mechanism of parturition."

Each topic is concisely but completely handled. For too feeble pains the author does not employ ergot,—using that drug only to cause expulsion of the placenta and firm contraction after delivery. He says, p. 161, "Ergot is hardly able to contribute to the expulsion of the child;" while, "in many cases, uniform and marked pains are produced by no remedy better than by opium," which he gives in grain doses, once or twice repeated. The use of the catheter between the child and the uterus, even after the rupture of the membranes, he highly recommends in feeble or absent pains. In regard to the method by external pressure, he advises it in true breech-presentations, in combination with traction, as being less likely than the latter alone to displace the arms of the child. In the method of accouchement forcé, the author, if dilatation by the hand fails, advises incisions of the os,—"*in primiparæ*, where the edges of the os are very sharp," doing the operation with blunt-pointed bistoury or scissors, curved on the side, incising two or more places. He says, or his translator says for him, "The incisions need not be too deep." And again, "It is known from experience that the incisions do not tear more:" which is comforting, if we could always rely on experience.

We quote from the author's description of what forceps should be (p. 172): "As regards the head-curves of both blades, the tips of the bow must not meet when the handles of the forceps are brought together, but should be distant more than one-third of an inch. The greatest distance between the bows must be 2.7 inches. The pelvic curve need not be very great, and is gradually to increase from the lock upwards to the lip." And again, "The ideal forceps would be such as allowed a sufficiently firm hold without exerting the least pressure upon the head."

On p. 174 we find five conditions given, all of which should be present in the application of the forceps. The fifth is that "The small fontanelle must be directed forwards." In commenting upon this afterwards, he says the fifth condition is very desirable, but not absolutely necessary. Another condition is that the head must have entered the true pelvis already. If immovable above the brim, he considers, even in the case of a normal head, in a normal pelvis, the instrument dangerous, "for the forceps can only lie transversely in the outlet, and the head, if possible, always so turns within the forceps that the blades lie on each side;" and, "unless the dimensions of the pelvic cavity are uncommonly great, the frontal bone of the child may, if powerful traction be made, be broken against the promontory of even a normal pelvis."

When we consider that the author has been quoted as an advocate of the doctrine that the occipital posterior positions rotate anteriorly in the grasp of the forceps, as a rule, we are surprised at the above, and at the following, from p. 178: "As long as the large fontanelle is directed forwards, the forceps are not to be applied."

After advising turning in face-presentations, whenever possible, he says (p. 179), "Even in head-positions in cases where both operations are practicable" (*i.e.*, forceps and version), "turning is always to be preferred." In other words, all cases of movable head, head not engaged at the brim, are to be turned.

We turn now to p. 180: "The application of the forceps in a contracted pelvis may be followed by the

saddest consequences to the mother and child." The panacea then, according to Schroeder, is version for all difficulties where version is practicable. In noticing, some time ago, the work of a British obstetrician, we characterized the treatment of the subject of the forceps as timid, and the views of the author before us on the same subject seem both timid and limited. Surely we do these things better in America! Is it because we employ better instruments? Do we not advocate the use of the forceps to overcome slight contraction of the brim? Is version a better resort? According to our author, it is not always a happy entrance into life. "When the breech is born, and the placental circulation disturbed, the mouth not being accessible to air, the first breath is followed by an inspiration of foreign bodies, and, consequently, by asphyxia. . . . It may also be caused by pressure on the cord." The author, therefore, advises the most rapid extraction, which he "considers without the slightest difficulties." He hastens, "not from the fear of not being able to resuscitate the child, but because, by the first inspiration, foreign bodies enter the air-passages, which may there produce a fatal inflammation." While the mother is uninfluenced by the method of delivery, or it is about as favorable as head-first labors, the child fares far otherwise. And, again, great stress is laid (p. 185) on the "foreign bodies drawn into the air-passages," which "may, within the first few days after birth, produce lobular pneumonia," and the prognosis is said to depend on the success of the treatment of the effects of premature respiration. We have no statistics at hand to show the number of children dying shortly after head-last labors, of lobular pneumonia, and can, therefore, only call attention to the above. It is our opinion, however, that children recovering from the asphyxia of cord-pressure have a much better chance of life than the above would seem to indicate.

We have here attempted a hasty notice of Chap. I., Part VI.

Perhaps no portion of the work is more clear and true than that on the induction and necessity of premature labor. As regards artificial abortion, in cases where the child cannot, by reason of tumors, or want of size in the pelvis, "pass through it anyway," "it must rest with the mother to decide, at the commencement of pregnancy, as well as at term, whether, for the sake of her offspring, she will place her own life in danger."

As to the merits of the translation, we say but little, leaving it rather for professed German scholars; but that its English is not always easily flowing, its obscurity sometimes the fault of the translator rather than of the author, is saying but part of the truth, if we believe, as we have some reason to, that certain unwarranted liberties of omission have been taken with it by the gentleman who has given it to the English-reading world. E. W. W.

CONJUGAL SINS AGAINST THE LAWS OF LIFE AND HEALTH, AND THEIR EFFECTS UPON FATHER, MOTHER, AND CHILD. By AUGUSTUS K. GARDNER, M.D. New York, G. T. Moulton, 1874.

"To the reverend clergy of the United States, who by example and instruction have the power to arrest the rapid extinction of the native American people, to prevent the brutalizing of their bodies and the degradation of their sensibilities, this work is most respectfully dedicated by the author."

For two years—we learn from the preface, written by one who signs himself "The People's Servant"—this work has been out of print. Probably long ere this time the children have been crying for it; crying in that place where Virgil heard their voices, lamenting the life they never knew.

The appeal to the clergy by a neat dedication is a 'cute way of securing the advent under moral auspices, and surrounded with a pious halo, of a book which, however, on nearer inspection may prove as little sanctifying as that peculiar luminosity observed at times about decaying fish and fungoid vegetation.

The clergy have never shown a willingness to deal with subjects of the kind. It is doubtful whether they can do so to advantage. One truly good man, now no more, made the attempt, and with the result that whenever his name is mentioned there rises in the mind the name of his book,—let us call it "The Alligator in the Hen-roost,"—and he goes down to posterity as its author no more fondly remembered for it, we fear.

The remedy lies, if anywhere, with the medical profession: its relations to the public, and *its* relations only, are such that it can touch the subject without indelicacy and without defilement, but it must be in some better way than by books sent broadcast over the land. The weapon, though useful, is too dangerous to be fired at random.

Too often, also, there lurks in the shadow of such attempts a deep and unworthy design,—professional advertisement, in its most sinister form. We do not say that this book implies it; we have seen others far better fitted to succeed in such an attempt; but such works are always to be regarded with suspicion, till proved honest and true.

The mere writing of such books is easy. Some slight acquaintance with French literature of a certain sort, free quotation, authorities cited from every direction, some discussion—to keep up the moral atmosphere—upon the Mosaic law, some newly-furbished hypotheses and startling assertions, and, lastly, a correct tone,—nothing vulgar. It was the boast of a certain writer of dubious novels that in all his prurient volumes there was not one improper word.

The language of the book is somewhat obscure in places, probably from the fear of offending delicacy. It has its theories, vague and wild enough at times; its quotations, wilder than itself. Like all other authors of like works, the writer has his say concerning the best methods of elevating the standard of the race. He believes that the musical development of the past twenty years owes its origin in this country to the advent of Jenny Lind, and the musical furor which she excited, influencing in mind and tastes the children procreated during that time. Like all other books of the kind that we have read, this one considers the native American race as going rapidly to decay and extinction,—which may be true in exhausted New England and over-stimulated New York, but is by no means so in the West, or even in our own quiet "village."

The subject of the increase of population and the prevalence of criminal abortion is extensively discussed. The doctrine of "moral restraint" is inculcated by the book, and its author lends his authority to the theory that in a majority of cases impregnation is practically impossible for a limited number of days in the menstrual interim; and with these two feeble weapons he would stem the ever-swelling flood of luxury, extravagance, and their imperious demands. We wish him success. However, wherever children are valuable for what they can do when men and women, where the fields are wide that wait for cultivation, and the woods are thick that wait for clearing, in short, where the struggle for life is against nature and not against man, there child-life is always and always will be held sacred and dear. The lamented man whose much-ridiculed advice was, "Go West," probably did more actually to prevent infanticide than has been done by the authors of the many books of which "Conjugal Sins" is one.

GLEANINGS FROM OUR EXCHANGES.

MERCURY IN SYPHILIS.—In a paper published in *The American Journal of Syphilography*, April, 1874, Jonathan Hutchinson, F.R.C.S., arrives at the following conclusions:

That mercury is probably a true vital antidote against the syphilitic virus, and that it is capable of bringing about a real cure.—That, in practice, a good many cases are really cured by mercury; the cure being proved by the restoration to good health, and, in some cases, by renewed susceptibility to contagion.—That the probability of cure depends upon the stage of development attained by the disease when the remedy is resorted to, and upon the perseverance with which it is used.—That, in order to secure the antidotal efficacy of mercury against syphilis, it is desirable to introduce a considerable quantity into the system, and to protract its use over a very long time.—That ptyalism and other evidences of the physiological action of mercury, so far from being beneficial, are, if possible, to be carefully avoided, since they prevent the sufficiently prolonged use of the remedy.—That in cases in which the patient shows an idiosyncrasy peculiarly susceptible to mercury, the indication is to reduce the dose rather than to omit the drug.—That it is impossible to begin the administration of mercury too soon, and that it should be resorted to without loss of time in all cases in which a chancre shows a tendency to indurate.—That many cases of indurated chancre, treated early by mercury, never show any of the characteristic symptoms of the secondary stage.—That in other cases of mercurial cure of the chancre, in which yet secondary symptoms do occur, they are usually milder than if allowed to develop without specific treatment.—That when mercury does not wholly abrogate the secondary stage, it exhibits a remarkable power in delaying it.—That delayed outbreaks of secondary syphilis are to be regarded rather as proof that the administration had not been sufficiently persevering than that the remedy was not efficient.—That it is probable that the risk of tertiary symptoms is in ratio with the severity and prolonged duration of the secondary stage.—That there are some grounds for believing that the tertiary symptoms of syphilis are both less frequent and less severe in those who have been efficiently treated by mercury than in others.—That mercury, cautiously given, does not, in a great majority of instances, do any injury to the general health, and that its local inconveniences may usually be prevented.—That the doctrine of the real antidotal character of mercury, in respect to syphilis, ought to lead to much more prolonged administration of it, with the hope of destroying utterly all lingering germs of the malady.—That most collected statistics as to the duration of treatment and freedom from relapse are misleading and worse than useless, because usually the treatment was far too short to be effectual.—That it has not yet been proved that there are any special forms of syphilitic disease in which mercury ought to be avoided, although, as a general rule, it is acknowledged that it must be used with more caution in all forms which are attended by ulceration than in others.—That iodide of potassium possesses little or no efficacy against either the primary or secondary form of syphilis.—That the efficacy of mercury is often most signally proved in cases which have utterly resisted the action of iodide of potassium.—That it does not much matter whether mercury is given by the mouth, by inunction, or by the vapor-bath, provided that, whichever method be selected, care be taken to avoid salivation, purging, etc.—That the doses usually resorted to for internal administration are for the most part too large, and thus often necessitate a premature discontinuance of the

remedy.—That if one method of administration does not proceed satisfactorily, another should be tried; and that in no case of difficulty should the vapor-bath be forgotten.

ACUTE DESQUAMATIVE NEPHRITIS DURING GESTATION (*Canada Medical and Surgical Journal*, April, 1874).—Dr. John Reddy reports the case of a woman, æt. 38, and in apparent good health, whom he was called to attend during the sixth month of utero-gestation. She had been thirteen times pregnant,—seven coming to maturity, and five aborting. For three weeks she had not felt the motion of the child, and during that time had been troubled with severe frontal headache, accompanied by debility, partial loss of vision, and occasional confusion of intellect. She had also suffered some pain across her loins, and had had nausea. The backs of her hands and her insteps were slightly swollen towards the close of each day. In twenty-four hours she was only passing three fluidrachms of urine, which was dark, smoky, and opaque, and contained forty per cent. of albumen, a quantity of blood-corpuscles and renal débris, and one or two dark casts.

She was ordered to take, every four hours, a mixture containing ten grains of acetate of potassium and three drachms of infusion of digitalis to the dose, also a pill of compound extract of colocynth and hyoscyamus as an aperient, and a lamp-bath for twenty minutes. The following day she passed three and a half drachms of urine of the same character as the first. The next day there was marked œdema of the hands, feet, and legs. The face began to look puffy, and she only passed four and a half drachms of urine. For the next six days her condition grew worse; the œdema increased; loose crepitant râles were heard about the base of the lungs; she had severe headache and much dulness of vision; she only passed from two to four drachms of urine daily, so that in eight days the total quantity passed was but three ounces. It was then determined to induce artificial labor, which was done by injecting tepid water between the membranes and the wall of the uterus. There was considerable hemorrhage before delivery took place, and the fœtus was found extensively decomposed. The placenta had undergone almost entire fatty degeneration. She reacted rapidly, and the next day passed over a wineglassful of urine. She was ordered vaginal injections of Condyl's fluid, \mathfrak{z} i to a pint of tepid water, and moderate doses of iron and quinine. The following day she passed seventeen and a half ounces of urine, slightly muddy, and containing about eight per cent. of albumen; the œdema had perceptibly abated, and her respiration was quite free. The next day she passed thirty-three ounces of urine of a pale straw color, normal under the microscope, and without a trace of albumen.

From that time she progressed steadily towards a cure, with no further trouble except an attack of crural phlebitis, which yielded readily to treatment.

It was very remarkable that no uræmic convulsions occurred during this case, when we consider the small quantity of urine passed, and the fact that many of the prominent symptoms, as headache, nausea, dimness of vision, etc., were present.

THE KAK-KE.—We have received a late number of the *Japan Mail*, containing an interesting description, by Dr. Hoffman, of a species of endemic disease, known as *kak-ke*, peculiar to the islands of Japan. The malady is said to possess considerable similarity to the Indian disease called *beri-beri*, and by the Dutch, and subsequently by other foreigners, was erroneously supposed to be identical with it. It makes its appearance regularly at the beginning of spring, first attacking only such persons as have suffered from it in preceding years, and on the approach of warm weather assails,

also, those whom it had hitherto spared. The characteristic symptoms of the disease appear to be pain and stiffness in the lower extremities, accompanied by a diminution of sensibility and cutaneous œdema, beginning with the ankle-joints and rapidly extending to the knees. In addition to these symptoms there is a simultaneous occurrence of violent palpitation of the heart, to which is occasionally superadded endocarditis. The patient shows a distaste for all pursuits, and more especially those which demand exercise of intellect, while a general sense of drowsy weakness is observable. With the approach of cooler weather, the symptoms tend to disappear, even without treatment, and a slight weakness, often accompanied by anæmia, is all that now remains of the complaint; and this symptom disappears, also, in the course of the winter. In the more severe cases, however, the cure is deferred and is often incomplete, insensibility and palsy of different degrees remaining, occasionally even to the extent of complete paralysis of the upper and lower extremities, with atrophy of the part affected. In other cases, anæmia and general debility, with trembling of the limbs, remain to mark the passage of the disease.—*Boston Medical and Surgical Journal*.

NEW [?] METHOD OF REVIVING PATIENTS ASPHYXIATED BY CHLOROFORM-INHALATIONS (*The Lancet*, March 14, 1874).—Dr. Campbell, of Paris, recommends, in a late number of the *Journal de Thérapeutique*, to place persons threatened with death from inhalations of chloroform head downwards and feet upwards for between ten and fifteen minutes. He considers that death arises through syncope due to cerebral anæmia: hence the advantage of inducing an artificial cerebral congestion. The usual efforts at mechanical breathing—excitement of respiratory nerves, the drawing out of the tongue, insufflation into the lungs, etc.—may be had recourse to concurrently. Dr. Campbell mentions only one case where this method succeeded: it was suggested by Nélaton during an operation performed at Paris by Marion Sims. It would appear that the late Professor Nélaton was the first surgeon who introduced this practice. The author also thinks that the inverted position tends to drive from the lungs and trachea pent-up vapors of chloroform, which were increasing the asphyxia. It might be asked whether the stagnation in the cerebral vessels of blood charged with chloroform may not do more harm than good in these cases. Nor is it proved that death occurs generally from cerebral anæmia. The single case mentioned by Dr. Campbell has not considerable weight; but the method should be tried when an opportunity offers, and if it succeed in a series of cases, full confidence will probably be reposed in it.

COD-LIVER OIL EMULSION.—Dr. George M. Beard asserts (*Boston Medical and Surgical Journal*) that the cod-liver oil is scarcely to be perceived in the following emulsion, if the latter be carefully prepared. He says, *inter alia*:

"It takes a long time to make it, and the majority of druggists will slight it unless they are assured it will be ordered in large quantities. The latest modification that I employ is the following. If desired, Fowler's solution may be added to it. One of my patients, a physician, has added strychnine to it.

"R Glyconin, \mathfrak{z} ix;
Ol. morrhue, \mathfrak{z} iv;
Spts. ammon. arom., \mathfrak{z} i;
Vini xerici, \mathfrak{z} ij;
Acid. phos. dil., \mathfrak{z} ss;
Ol. amygdal. amar., gtt. ij.;
dissolved in alcohol, \mathfrak{z} ij.—M.

"Put the glyconin first in the mortar, then add the

oil by drops, stirring briskly all the time. When this process is completed, you will have a mass looking like and having the consistency of soft butter. Then add the other ingredients in the order mentioned; add them slowly, stirring all the time. The glyconin is made by beating yolks of eggs with a spatula until they are well broken, then add an equal measure of glycerin. It requires one or two hours to make it."

NERVOUS SEDATIVES IN GONORRHEA (*Irish Hospital Gazette*, March 16, 1874).—Dr. Parona (*Giornale delle Malattie Veneree*) has made an extended trial of chloral as an injection both in the gonorrhoea of men and in vaginal blennorrhagia, and speaks of its value as a sedative, and also as an astringent. The strength of the injection is one gramme, or one gramme and a half, of chloral to one hundred grammes of water. The injection is used three times a day, and retained as long as possible. The best time to commence it is when the acute symptoms are subsiding, and it then not only relieves the pain and distress on passing water, but also removes the discharge. Dr. Bligh (*The Practitioner*, February) speaks highly in praise of the efficacy of bromide of potassium, both internally and locally, in the treatment of gonorrhoea. He prescribes the bromide in ten-grain doses three times a day, in combination with potassium bicarbonate and tincture of hyoscyamus, from the inception of the disease, and orders a syringeful of the following injection every four hours:

R Potassii bromidi, ʒii;
Glycerinæ, fʒss;
Aquæ dest., fʒiss. M.

A draught containing about half a drachm of the bromide in an ounce of camphor-mixture, at bedtime, he found to allay the chordee almost to a certainty. He claims for the bromide the power not only of diminishing the secretions and assuaging the pain of all inflamed mucous membranes, but also of producing a *special* sedative effect upon the organs of generation.

PERINEAL LITHOTRIPSY (*The Medical Record*, March 30, 1874).—Dr. Ernest Krackowizer reports three successful cases of perineal lithotripsy, which he considers to be superior to median lithotomy chiefly for two reasons: 1, in that it dilates the wound-track, the prostatic portion, and the neck of the bladder, in a more gentle and gradual manner than it is possible to do with the finger; and 2, in that it renounces beforehand the attempt to extract a stone beyond the diameter of three-fourths of an inch, considering that the track established by median lithotomy cannot be stretched safely beyond the diameter of one inch without exposing the patient to the immediate and subsequent danger of tearing and contusing the parts which constitute the way for extracting the stone.

TORSION IN AMPUTATION (*The Lancet*, March 21, 1874).—Mr. Thomas Bryant highly recommends the practice of torsion as preferable to the use of the carbolized catgut ligature. He instances a case of amputation of the fore-arm where all the arteries were twisted except the interosseous, which was ligated, and from which severe secondary hemorrhage occurred at the end of six days. He says at Guy's Hospital there have now been upwards of two hundred cases of amputation of the thigh, leg, arm, and fore-arm, in which all the arteries have been twisted (one hundred and ten of these having been of the femoral artery), and no case of secondary hemorrhage.

RESTRAINT OF HEMORRHAGE DURING OPERATIONS ON THE MOUTH (*The Medical Examiner*, April 1, 1874).—Dr. E. Andrews suggests that the troublesome and annoying hemorrhage which almost always attends operations on the mouth, and which is so difficult to

control, can be effectually restrained by the use of an ether-spray apparatus. If the spray be directed upon the part to be operated on, the cold thus produced will thoroughly contract the vessels, and at the same time the general anæsthesia is kept up, the patient constantly inhaling the vapor. Dr. Andrews has performed uranoplasty in this manner with great freedom from annoyance.

STYPTIC COLLODIUM.—The *Dublin Medical Press and Circular* gives the following formula:

R Tannic acid, 2 ounces;
Alcohol, 4 fluidounces;
Ether, 12 fluidounces;
Canada balsam, 1 drachm;
Pyroxylin, 1 drachm, 2 scruples.

Dissolve the tannin in one ounce of the alcohol, mix the Canada balsam in the ether, add the remaining alcohol, and in the mixture dissolve the soluble cotton.

CHLORAL IN CHOLERA MORBUS.—Dr. Louis B. Bouchelle (Georgia) has employed chloral in cholera morbus for the past two years with marked success. He states that in the case of adults a single dose of twenty to thirty grains has in every instance served to quiet the stomach and bowels, and the patient drops into a refreshing slumber, from which he wakes in a few hours relieved.—*The Southern Medical Record*, January, 1874.

MISCELLANY.

WILLOUGHBY SMITH, the electrician, has recently discovered a most curious action of light in altering the electrical resistance of a metal. In experimenting for a special purpose, with some small rods of selenium, about one-twentieth of an inch in diameter by three or four inches in length, enclosed in glass tubes, with platinum terminals, he found that their electric resistance varied most capriciously, and to a very great extent. He finally traced the disturbance to the action of light, —finding that when the rods were enclosed in a dark box their resistance was perfectly normal, while even a slight exposure to light immediately reduced it some ten or fifteen per cent. On burning a magnesium ribbon at a distance of nine inches from the selenium rod, which, to cut off all disturbing action of heat, was immersed in its tube to a depth of several inches in a basin of water, the conductivity of the bar was at once increased nearly threefold, remained constant while the light lasted, and as soon as the flame went out immediately returned to its original value. The discovery excites great interest, and opens an entirely new field for investigation.—*Druggist's Circular*.

DISCOVERY OF BISMUTH.—The Paris correspondent of the *London Chemist and Druggist* states that M. Carnot, a mining engineer, reports the discovery of a bed of bismuth in the mountainous region which separates the departments of Bresse [sic: Corrèze?] and Dordogne. This had been observed by him since 1867, but only recently has he found that it could be profitably worked. It is found in combination with lead, antimony, iron, and calcium. M. Carnot has also devised a better process for the extraction of the bismuth in a

state of perfect purity. Already some two hundred and fifty kilogrammes have been supplied to the Pharmacie Centrale, Paris. This discovery is very fortunate. The high price of bismuth is consequent partly on the increased appreciation of its value as a medicine, and partly on the fact that an important source of its supply—namely, the deposit of Saxony—is nearly exhausted. At present the Bolivian mines almost exclusively supply commercial requirements, but no country will grudge France a happy turn in this or in any other respect.—*Boston Journal of Chemistry*.

A LEAD AND ZINC BATTERY.—A new form of galvanic battery invented by Pierlot is thus described in *Comptes-Rendus*: In a suitable glass or earthenware vessel is placed about a pound of chloride of lead, into which is inserted a plate of lead with a varnished lead wire attached. In the other part of the vessel is inserted an amalgamated zinc plate about nine millimetres thick, covered with a bag of parchment paper. Every two or three months water is added. The current is said to be strong and constant.—*Journal of Applied Chemistry*.

AN ODD EPITAPH.—The following epitaph is to be found in Braken churchyard, Shetland:

He was a peaceable and quiet man, and to
All appearance a sincere Christian.
His death was very much regretted,
Which was caused by the stupidity of
Laurence Collochlin Clothister, who
Gave him saltpetre instead of Epsom salts,
Of which he died in the space of three
Hours after taking a dose of it.

—*Boston Journal of Chemistry*.

CHOLERA AND THE CHINESE.—Dr. Taylor, a returned missionary from China, reports that during a residence of many years among the Chinese no cases of cholera came under his observation; and this absence of the disease he attributes to the fact that tea is the beverage of the country, and consequently nearly all the water which the inhabitants drink has been boiled.—*Dr. E. McClellan, in the American Practitioner*, March, 1874.

FOR COLD IN THE HEAD.—Hamilton recommends to mix carbolic acid 10 drops, tincture iodine and chloroform each 7.5 drops. A few drops are poured into a test-tube and heated over a spirit-lamp, and when it begins to evaporate it is placed under the nostrils. Two minutes afterwards the operation is repeated. Sneezing at first results, but relief soon follows.—*Journal of Applied Chemistry*.

TREATMENT OF CHRONIC ECZEMA OF THE GENITALS.—Dr. De Montmya recommends the use of tincture of iodine in the treatment of chronic eczema and intertrigo of the genitals, more especially combined with the use of a lotion of one part of corrosive sublimate to two hundred and fifty of water, a few drops of spirit being used to dissolve the corrosive sublimate.—*Druggist's Circular*.

ACCORDING to the *Independence Belge*, the ex-Emperess of Mexico remains in the same mental condition, her bodily health being very good.

COTTON-SEED OIL.—It is said that in the United States over 150,000 tons of cotton-seed are used, annually, for the manufacture of oil. The greater portion of this product goes to the olive-growing districts of Europe, from whence, after certain manipulations, it is returned as olive oil.—*Canada Pharmaceutical Journal*.

A SICK man, slightly convalescent, was asked by a pious friend who his physician was. He replied, "Dr. Jones brought me through." "No, no," said his friend, "God brought you out of your illness, not the doctor." "Well, maybe he did; but you can bet the doctor will charge for it."

SOME person said to Sterne that apothecaries bore the same relation to doctors that attorneys do to barristers. "So they do," said Sterne; "but apothecaries and attorneys are not alike, for the latter do not deal in scruples."—*Baltimore Physician and Surgeon*.

ACCORDING to Medical Director Joseph Wilson, U.S.N., 81,000 lives were destroyed by malaria in making the Panamá Railroad, only forty-six miles in length; one man for every yard of the track.

In the official examination of the hogs killed in the duchy of Brunswick during 1873, out of 92,605, 19 were found affected with trichina, and 18 with other diseases.

A POPULAR doctor in Chicago was presented with a silver-mounted skeleton, on New Year's day, by his admiring patients.—*Atlanta Med. and Surg. Jour.*

THE LATEST NOVELTY.—"St. Vitus's dance is one of the most novel of the diseases of the nervous system."—*Medical and Surgical Reporter*.

AMONG the advertisers in the London *Lancet* we notice Waukenphast [walking fast?] & Co., makers of tourists' boots.

ACCORDING to Johnston, 30,000,000 pounds of coca-leaves are annually used in South America.

NOTES AND QUERIES.

AMERICAN MEDICAL ASSOCIATION.

Arrangements have been made with the Lehigh Valley and Erie Railways to carry delegates to the session at Detroit, at reduced fare, via Niagara Falls and Canada. All who desire to avail themselves of this opportunity should address the undersigned at an early day.

W. B. ATKINSON, M.D.,
Permanent Secretary,
1400 Pine Street, Philada.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 14, 1874, TO APRIL 20, 1874, INCLUSIVE.

BAXTER, J. H., CHIEF MEDICAL PURVEYOR.—To report to the Surgeon-General for assignment to duty. S. O. 83, A. G. O., April 16, 1874.

MCCLELLAN, ELY, ASSISTANT-SURGEON.—To carry out provisions of joint resolution of Congress, approved March 25, 1874, on the recommendation of the Surgeon-General, detailed to inquire into and report upon the causes of epidemic cholera. S. O. 85, A. G. O., April 18, 1874.

SATURDAY, MAY 2, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE ON SEBORRHŒA CAPITIS.

BY LOUIS A. DUHRING, M.D.,

Clinical Lecturer upon Diseases of the Skin in the University of Pennsylvania, and Physician to the Dispensary for Skin Diseases, Philadelphia.

Reported by DR. ARTHUR VAN HARLINGEN.

THE patient whose case forms the subject of our study to-day complains of an affection, not indeed severe, and certainly not dangerous, but yet one of such character as to claim close study of its features and careful treatment if we would succeed in its cure.

He is, you observe, a man of middle age, pale, and evidently out of health. A weaver by occupation, he is confined much of the time to a dark, unwholesome apartment; his hygienic surroundings, in fact, are bad.

The disease for which he seeks relief we find to be localized in the scalp, showing itself on the surface in the form of a copious accumulation of small, pearly-white, greasy-looking scales.

The reproduction of these scales is attended with considerable-itching, and is so rapid that, although the scalp may be thoroughly cleansed in the evening, yet by the next morning they are present again as abundantly as ever.

The duration of the affection is about three months, or rather about that length of time has elapsed since the itching and scaliness first became so annoying as to attract the patient's attention. It is probable that its origin may be referred to a much earlier date.

These facts in the history of the case having been ascertained, let us examine the appearances presented, and determine, so far as we may, its exact nature.

Have any extraneous causes of irritation, such as might produce a condition like the present?

As to stimulant applications, our patient informs us that none have been made; but as to pediculi, the only other likely source of external irritation, some examination will be necessary.

The diagnosis of phtheiriæsis is not difficult, since either the unmistakable pediculus is present *in propria personâ*, or its representative ova, known by the following characteristics, may be discovered.

The ovum of the *P. capitis* is a small, pear-shaped, grayish-white body, about the size of a grain of sand, and is found attached quite firmly by its smaller end to the hair at a considerable distance from its insertion into the skin. Examination of our patient's scalp shows the absence of living pediculi; but are these grayish particles sticking to the hairs at various points, ova? At first glance, they certainly appear to be such; but on closer inspection they are seen to have an irregular shape, to be easily brushed off from the hair, and, in fact, to be in all

respects identical with the scales on the surface of the scalp.

Phtheiriæsis, then, the only remaining source of irritation, being excluded, let us proceed to an examination of the eruption itself, with the object of ascertaining which, among several affections likely to be found in this locality, we have in the present case.

There are only three diseases occurring on the scalp in a form resembling the one before us: they are *psoriasis*, *eczema*, and *seborrhœa*. It would be impossible to give such a verbal description of these affections as would enable you always, and under all circumstances, to recognize and distinguish them; experience alone will enable you to do that. Their leading characteristics, however, you should certainly be acquainted with. They are as follows:

Psoriasis capitis manifests itself in the form of dry, white scales, scattered through the scalp. It usually extends a little beyond the space covered by long hair, so as frequently to form over the forehead, ears, and neck, a whitish or reddish border encircling the scalp. It is not apt, as a rule, to itch so intensely as the other two affections under consideration, and when occurring in the head is almost invariably found in other parts of the body, especially around the elbow- and knee-joints.

Eczema capitis may occur either in the vesicular or squamous form. If it occurs in the former, the peculiar structure of the scalp modifies to some extent the appearance of the disease.

In mild cases, this variety presents itself in the form of yellowish, friable crusts, consisting of epithelial scales mingled with dried serum. On raising these crusts, the surface beneath is found to be red, shining, and moist. In severe or neglected cases the secretion of the sebaceous glands mingles with that of the vesicles, and the products of disease, becoming decomposed, give rise to a peculiar and disgusting odor. The hairs also become matted together, and the most severe form of the affection is called in some countries "*plica polonica*," a mixture, in fact, of *eczema*, *seborrhœa*, and filth.

In the squamous form of *eczema*, the scalp is red, and covered with fine, dry, white scales.

Seborrhœa capitis is characterized by the abundant production of scales in the same manner as the two diseases just spoken of, but these scales are seen, on careful inspection, to possess quite a different character from those of *psoriasis* or *eczema*. They are numerous, pearly-white, and have a decidedly greasy lustre and feel. They have also a certain cohesiveness, which causes them to accumulate in masses, but they have no tendency to produce matting of the hair.

On raising a patch of *seborrhœa*, we find the underlying skin red indeed, and somewhat shining, but with no appearance of moisture, as with *eczema*.

A careful examination of the patient before us will justify the assertion that we have here a well-marked case of the last of these three diseases,—*seborrhœa capitis*,—*seborrhœa* of the head.

There are two varieties of *seborrhœa*: *seborrhœa*

oleosa and seborrhœa sicca. The former is characterized, as its name would indicate, by increased fluidity of the sebaceous secretion, which is also poured out in such quantity that the affected skin frequently looks as if it had been freshly anointed with oil. This variety is most usually found on the face, although it sometimes occurs on the scalp and elsewhere. When persons who are exposed to dust or dirt become subjects of this variety of the disease, the visage presents a peculiar and constant grimy appearance, which nothing but frequent cleansing can prevent.

In seborrhœa sicca, on the contrary, the more solid constituents of the sebum predominate and the secretion assumes an inspissated condition; hence the name, dry seborrhœa. It is the latter variety of seborrhœa which we have in the case before us.

This affection is not invariably confined to the scalp; on the contrary, we frequently see it on the face, and, in fact, it may occur in any part of the body where there are sebaceous glands. It is decidedly more common, however, in the scalp, since in this locality the sebaceous glands are more numerous and active than elsewhere.

When seborrhœa sicca occurs in non-hairy portions of the body, its appearance is decidedly modified; fewer scales are detached, and the diseased surface usually presents simply a circumscribed patch of congested skin, with slightly roughened cuticle.

The pathology of the affection is as follows: When from any cause the sebaceous glands take on abnormal action, not only is their secretion altered in one way or another and poured out in increased quantity, but their epithelial investment itself becomes to a certain degree affected, and the lining cells are reproduced and thrown off with unhealthy rapidity. It is the cells constituting this lining membrane, as well as the inspissated sebum which mats them together, which go to form the pearly-gray scales observed on the surface of the skin.

The name of the disease—seborrhœa—is derived from the Greek, and signifies a flow of sebum to an abnormal amount, this being the characteristic feature of the affection.

The rapidity with which the scales are thrown off is astonishing. Our patient has just told us that in a very short time the scalp may become entirely covered with them. This rapid proliferation of the lining epithelium with abnormal and excessive secretion from the sebaceous follicles may go on for years if unchecked, and finally the disease may involve the hair-sheaths themselves, and cause the death of the hair. Seborrhœa becomes in this way one of the most frequent causes of premature baldness.

The origin of the affection is usually to be found in some defect of nutrition, such as chlorosis or anæmia in both males and females. In the latter, irregularity in the performance of the menstrual function is a frequent cause. In fine, all those conditions of want of health which are indicated by cold hands and feet, as well as various forms of indigestion, may be indicated as among the known causes of seborrhœa.

Our patient is evidently anæmic, and badly nourished, and our treatment of his skin-trouble will be based upon the removal of this condition. So far as he is able to follow our advice, he will take fresh air and exercise. His food shall be nutritious, with strict avoidance of pastry, fat meats, or any form of diet which may be found to cause indigestion.

As regards medicinal treatment, he will be ordered ol. morrhœæ; a tablespoonful of the oil to be taken about an hour after ordinary meals. If this does not derange the stomach or digestive apparatus, he will be directed to continue its use for several months, intermitting it for a short period perhaps at intervals. The cod-liver oil is often of decided benefit in these cases, and may be relied upon as a valuable auxiliary. But the medicine which is of paramount importance and of unquestionable service in the majority of cases of seborrhœa is iron; it is indicated and will be of service in the case of the patient before us. He will be ordered four grains of the tartrate of iron and potassium in sweetened water, to be taken thrice daily directly after eating. The use of this preparation will be persevered in for some time; several months at least.

We shall scarcely look for much improvement before a month's time. Seborrhœa is slow to get well; it is a disease which has to be treated with care and discretion, requiring time to undergo change. Until a certain alteration has been produced in the constitution of the patient, it is useless to expect a cessation of the process; for the disease in the case under consideration is no mere local trouble, but a state emphatically associated with his general poor health and improper condition. Relying upon the oil and iron for the internal treatment, together with hygienic measures, it will be necessary at the same time to employ local treatment as auxiliary means of relief. It is important to keep the scalp thoroughly clean and free from the products of the disease. To get rid of the scales we shall order him some alkaline liquid preparation. A very suitable wash for these cases is the tinct. sap. viridis,—a solution of *sapo viridis* in alcohol in the proportion of two ounces of soap to one of alcohol. This is a valuable and efficacious alkaline wash for various conditions of the scalp, and is of particular service in seborrhœa capitis. It is to be rubbed upon the head by means of a piece of flannel, adding a sufficient quantity of water to the scalp from time to time to make an abundant lather. This is thoroughly rubbed into the affected parts, and after ten or fifteen minutes completely washed out of the hair by means of an abundant supply of warm water, care being taken to rid the scalp entirely of suds. The scales will by this means be completely removed. The hair and scalp should now be dried with a soft towel until all moisture has disappeared. Some oily or fatty preparation is now to be applied directly to the scalp, and to the hair as well, in order to counteract the effect of the alkaline wash, which tends to produce shrinkage of the skin. We shall order for our patient an oil composed of one part glycerin, one part ol. ricini, and two parts alcohol, to be worked into the scalp after each washing with the soap preparation.

There are cases of seborrhœa, however, where the products of disease have been allowed to accumulate to such an extent that they form quite a crust. In such cases a quantity of olive oil—say a teacupful—should be well worked into the scalp, and the head covered with a night-cap. If this is done at night, the crusts and scales will have become so far softened by the next morning that the wash above mentioned may be successfully used.

Finally, you should remember that in such cases as these of old standing, and where the disease has made much progress, many hairs will have become loosened from their sheaths, and will remain attached to the crusts only. Of course, the first time the patient's head is thoroughly cleansed all these detached hairs come away, and the effect at times is somewhat startling. It should always be ascertained if many hairs have become loosened or entirely separated before the cleansing process has been commenced, that the patient may be warned of the probable result.

ORIGINAL COMMUNICATIONS.

INTRA-UTERINE MEDICATION, — A NEW APPLICATOR.

BY H. E. WOODBURY, M.D.,

Washington City, D.C.

IN the *Medical Times* of April 4, 1874, "Subscriber" expresses his conviction that by Dr. Goodell's method applications cannot be made to the cavity of the uterus. After a careful perusal of Dr. Goodell's paper, I fully concur with "Subscriber" in his belief that before the mop reaches the fundus the fluid it contained will have been pressed out and taken up by the cervix.

Since the publication of my article in the *Medical Times* (April 26, 1873), "A New Instrument for treating Diseases of the Neck and Cavity of the Womb," I have been studying this subject carefully, with the view to construct an instrument by means of which applications may be made to the uterine cavity, thoroughly, effectually, and to which the objections entertained by many as to intra-uterine injections may not apply.

While my experience with the uterine injector referred to above has been extremely satisfactory, I have been anxious, if possible, to improve upon that method, and now present to your readers, and to "Subscriber," a safe and sure instrument for the accomplishment of the desired end.

My instrument, the applicator, very much resembles the injector in shape, so far as the glass tube is concerned, the only difference consisting in this, that in the applicator the openings at both terminal extremities are of the same diameter, while in the injector one of these is capillary. The edges of these openings are well rounded by heat.

Through this tube I pass a piece of steel wire about two inches longer than the tube, the temper being removed from the last two inches of this,

so as to permit of its being bent to any desired curve.

The instrument is used as follows. We first moisten the end of the wire, and wrap closely around it just enough of cotton to admit of its being drawn back into the tube without difficulty. The cotton is then dipped into fuming nitric acid, tinct. iodine, strong solution of carbolic acid, or any other fluid we may select, and withdrawn into the tube. The end of the tube is well wiped, and through the speculum introduced into the womb, dilatation of the ostium internum being sometimes necessary, in order that the tube may be passed. When the tube has entered as far as is necessary, we gently push the mop into the cavity. Thus it will be seen that our remedial agent is entirely under our control, and the cotton is not "squeezed dry" by coming in contact with the mucous surface of the cervix, as in Dr. Goodell's method.

If deemed desirable, a few drops of the fluid may be drawn into the tube, if we wrap enough of cotton on the end of the wire to make it act as a piston. This will flow out slowly, guttatim, when the wire is pushed in, and not with the force of an injection.

I have used the applicator in several cases, with entire success. No unusual irritation has attended its use. The introduction of the solid nitrate of silver, as recommended by Goodell and others, into the uterine cavity, is often attended with unpleasant results. The chemically-pure nitric acid applied by my method seldom occasions any other sensation on the part of the patient than a feeling of warmth in the organ, and the promptness with which the symptoms yield to this mode of treatment is in the highest degree satisfactory. I feel confident that in this instrument the desideratum has been attained, and that the profession, after a fair trial, will give it their unqualified approval.

LEAD-POISONING FROM EATING PRESERVED FRUITS.

BY T. HALE STREETS, M.D., U.S.N.

A CASE of lead-colic occurred on board the U.S. steamer Portsmouth, in the person of Mr. Dupleman, the apothecary. Mr. D., who is likewise a chemist, discovered the source of the poison to be in the canned preserved fruits which he had been eating.

As "an ounce of prevention is worth a pound of cure," a few words of caution here will not be inadmissible.

Tin is cast into various forms, and is alloyed with several metals for domestic and other purposes. Tin cans are made of sheet iron coated with tin; a little lead is added to give it greater toughness. After the opening of the tin cans containing preserved fruits of any kind, as apples, plums, gooseberries, currants, cranberries, oranges, etc., etc., they should be emptied at once into some non-metallic vessel, as these fruits contain citric and malic acids abundantly, which will, with the help

of the atmospheric air, act upon the tin- (lead-) coated surface of the can, and become in consequence poisonous.

A piece of the can was tested with the blow-pipe, and the charcoal support became covered with the yellow oxide of lead. The plum-jam, which was the substance examined, had, after standing three or four days in the opened tin can, a very sour taste, and a nauseous, metallic after-taste.

To a solution in nitric acid there was added first, sulphuric acid, which gave a white precipitate of sulphate of lead; second, hydrochloric acid, which gave a white precipitate of chloride of lead; third, chromate of potassium, which gave a yellow precipitate of chromate of lead.

TWO CASES IN WHICH ESMARCH'S BANDAGE WAS APPLIED.

BY H. CULBERTSON,

Assistant-Surgeon U.S.A., Retired.

CASE I.—S. C., a young lad, aged 18 years. In January, 1872, took cold, and incurred a general inflammation of the periosteum of both tibiae, which disease involved the lower epiphysis in both limbs, did not destroy the integrity of the left, but impaired greatly the motion of the right ankle. By free incisions and other treatment, the diaphysis of the left tibia was preserved; but, although the same means were employed with the other leg, the shaft of the right tibia became necrotic to a limited extent. A sequestrum formed about the medullary canal, small in diameter, and the entire length of the shaft. Here and there were dead portions of the surrounding tibia, in patches, one an inch square, which connected with the disorganized medullary canal, and through which were openings (sinuses) leading to the surface of the leg. The tibia itself was enlarged and hardened, but no new bone was deposited about it. The interior of the bone was irregular in outline, and there was quite a cavity at the upper end of the diaphysis, and the endosteum was destroyed. It would seem clear that there was in this limb endosteitis as well as periosteitis, that the endosteum and a very thin layer of bone around the medullary canal, with here and there portions of the entire thickness of the bone, were destroyed by the inflammation. During the last two years the internal dead bone became absorbed to a narrow portion (not over one-fourth of an inch in diameter), and the removal of its animal matter rendered it so brittle as to crumble upon light pressure between the fingers. There were six or eight sinuses, which discharged moderately. To remove these necrotic portions of bone, the following operation was performed, March 11, 1874, there having been previously improvised an elastic bandage six yards in length, and made of garter-elastic three-fourths of an inch wide, three widths being sewed together when the material was stretched:

The patient having been chloroformed, the bandage was applied tightly, and then the fillet above it, at the lower third of the thigh. An incision was then made along the middle of and down to the tibia, the periosteum separated, and, with a centre-bit and carpenter's brace, a round section of the bone was bored out at three different points along the tibia, and the intervals cut out between these with a bone-chisel, so that there was a gutter five and a half inches in length and three-fourths of an inch in width, which reached down to the internal cavity of the bone. All the diseased bone was removed and the cavity smoothed up with a gouge, and cleansed,

and powdered alum thrown in freely, and finally it was lightly packed with dry cotton, a compress placed over the cotton, and a bandage over all. It required one hour to complete the operation, and scarcely any blood was seen during its performance. When the fillet was loosened, the bone bled for a few moments only. The next day the compress was removed, a simple bandage applied, and cold-water dressings employed. After the cotton separated, the cavity was dressed with flaxseed oil and carbolic acid. Acute pain in the limb followed for some days, but was controlled with free doses of morphine. The patient was given at once tr. ferri chloridi and quinine. No unfavorable complications resulted, and now (thirteenth day) the cavity is granulating, and the patient's general system is in good condition. The fever was controlled with tr. veratri viridis.

Drs. C. C. Hildreth and E. D. Safford, of this city, assisted in this operation.

Case II.—John W. S., æt. 32, incurred, August 29, 1873, a compound dislocation of the right ankle-joint from his foot becoming caught in some portion of a threshing-machine. The dislocation was reduced, but very active inflammation of the joint followed, and in ten days gangrene of the soft parts upon the outer side of the foot ensued, from the mechanical injury. The inflammation resulted in caries of the tarsus (excepting the os calcis) and the articular ends of the tibia and fibula. The joint was enlarged, and several sinuses discharged thin and unhealthy matter. The leg was much wasted. The general health of the man was not greatly impaired.

March 13, 1874.—The patient having been chloroformed, the bandage applied, and the fillet secured, with a view of excising the joint if possible, we made the external incision of Moreau over the external malleolus, separated the soft parts and periosteum, and sawed off the external malleolus. We found this and the fibula inflamed, softened, and carious as high as two inches and a half, also that the astragalus was carious and infiltrated with matter, and the other bones of the tarsus inflamed, and some of them softened; and subsequently that the tibia was diseased as high as the fibula. These facts having been ascertained, it was decided to amputate the limb, which was done at the point of election. During the operation scarcely a drop of blood was seen, until the fillet was removed. This patient reacted well, and I believe has done well since the operation.

Drs. E. Van Alta and O. M. Norman, of Uniontown, Ohio, assisted in this operation; also Dr. Axline, and a student, John Axline. The accident occurred in a distant part of Ohio.

ZANESVILLE, OHIO, March 26, 1874.

A CASE OF COMPLETE STRICTURE OF THE LARGE INTESTINE.

BY K. T. STABECK, M.D.,

Davis, Ill.

MRS. A., æt. 40 years, was treated for anteversion of the uterus for the past two years. For two months she wore one of McIntosh's supporters, but without any satisfactory results. Last October she was troubled with constipation of the bowels, and began to use various pills put up by patent-medicine men, with the result of irritating the mucous membrane of her stomach and intestines. This trouble increased up to January, 1874. At times she would be very constipated, and could pass nothing without the use of violent purgatives. There were also more or less swelling and tenderness on pressure. The symptoms increased, and

in the latter part of February she was seriously ill. There were very great tympanites, and frequent vomiting; food being thrown up almost always two or three hours after it was taken.

Cathartics and injections were administered, but gave no relief. For a period of two months she had no passage from her bowels. For seven months she vomited feces every day. She failed gradually, but without apparent inflammation of the peritoneum or intestines, and died in March from exhaustion. Post-mortem examination revealed a complete stricture at the angle of the transverse and descending colon, where there was a fibroid growth, not ulcerated, and apparently springing from the coats of the intestines.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. R. F. LEVIS.

Reported by J. B. ROBERTS, M.D.

SUICIDAL WOUND OF THE LARYNX.

A SAILOR while at sea endeavored to commit suicide by cutting his throat, but the attempt proved unsuccessful; and he was, after a few days, brought to the hospital for treatment. The incision extended across the throat at the level of the larynx, making a large oblique opening into its cavity. He has no voice except on closing the abnormal aperture, which is valvular, by inclining his head forward on his chest.

Suicidal attempts on the throat are generally cuts across the larynx or upper part of the trachea, where a mortal wound is not very likely to be inflicted, since there are but few important structures lying superficially in that region. The great vessels of the neck, emerging from the thorax behind the sterno-clavicular articulations, press obliquely backwards among the muscles, gradually receding from the surface; so that when an incision is made high up the knife does not strike any important artery, unless, possibly, the superior thyroid. Throwing the head violently backwards at the moment of making the suicidal cut, tends also to draw the cervical vessels back out of the reach of the knife.

If the cut is made across the lower part of the neck, division of the recurrent laryngeal nerve and of the inferior thyroid and carotid arteries may take place, from the latter of which profuse and fatal hemorrhage would follow.

The immediate and urgent duties of the surgeon in cases of cut-throat are to arrest arterial and venous hemorrhage; to free the trachea and fauces of clots of blood, inverting the body, if necessary, to facilitate their removal, and, should respiration fail, to resort energetically to means for artificially sustaining it.

Even if death do not occur from hemorrhage into the air-passages or from general loss of blood after cut-throat, there are still complications which may arise, of sufficient gravity to imperil the life of the patient. Inflammation that follows the injury may give rise to sufficient general tumefaction and oedema within the larynx and trachea to prevent the ingress of air to the lungs, and cause death from asphyxia, as in a case of cut-throat involving the larynx, in which Dr. Levis was obliged to perform tracheotomy thirty-six hours after the injury, to relieve such complication, which threatened the patient's life. After the possibility of this occurrence has passed, and the wound begins to heal, the formation of an inordinate amount of granulations or the contraction consequent upon cicatrization may

again place life in jeopardy from obstruction to respiration, and necessitate the opening of the trachea.

Dr. Levis once saw a case of homicidal cut-throat in which the knife, having been drawn across the throat just above the hyoid bone, severed the anterior attachments of the tongue, to such an extent that the organ fell backward, covering the opening of the glottis, and producing almost fatal dyspnoea. This trouble was relieved by drawing the tongue forward with a hook, and retaining it in that position until sufficient union had taken place to preclude the possibility of its recurrence. There are also cases on record where the epiglottis, having been partially cut off, fell into the chink of the glottis, and caused death.

When this man was admitted to the hospital, about three weeks ago, the wound gaped so widely that deep sutures were put in to draw the parts together, and the head was bent forward upon the chest to keep the edges in apposition. The healing process has gone on favorably, however, and he can now talk quite well, though the external wound is not closed entirely, for the finger can be introduced between the thyroid cartilage and the hyoid bone. He says that he has no trouble, except that swallowing hard substances gives pain by the food, during its passage through the oesophagus, pressing against the inflamed larynx.

Although he is doing so well at this time, it is not improbable that he may hereafter have secondary trouble from cicatricial contraction causing narrowing of the windpipe and interfering with respiration. Should such constriction eventually occur, it may be dilated by the occasional passage of a bougie.

Permanent fistulous openings occasionally remain as a result of laryngeal or tracheal wounds, particularly when there has been loss of substance from the cutting away of fragments, as in repeated hacking with a razor. Constriction at the upper part of a wound, by impeding respiration, may also keep open a fistulous orifice below. When no such constriction exists, and there is no oedema within the respiratory tube, the edges of the fistule may be freshened and brought together by sutures; but if the superficial tissues be tense and cicatricial, a plastic operation by taking integument from the surrounding space may become necessary.

HYPERTROPHY OF THE PROSTATE GLAND, AND ITS COMPLICATIONS.

An old man complained of difficulty in emptying the bladder, stating that he suffered severe pain on commencing to urinate, and was obliged to strain a great deal to effect complete evacuation.

From the age of the patient, and as he had trouble in starting the stream of urine, it was conjectured that the trouble was dependent on a hypertrophied condition of the prostate gland. The prostate was accordingly examined by passing the finger into the rectum. By this manipulation the lateral lobes of the prostate were found to be greatly enlarged, filling up the pelvis like a foetal head in the vagina, so that it was impossible to get the finger around the whole circumference of the gland. A catheter was introduced into the bladder to determine whether there was a corresponding hypertrophy of the third or middle lobe, which, if enlarged to any marked degree, may, from its situation, immediately within the neck of the bladder, present serious obstruction to the flow of urine.

In this case the third lobe was not increased in size so much as the other lobes, as was made evident by the comparative ease with which an ordinary metallic catheter passed into the bladder.

It is not at all unusual to find in old men prostatic disease and consequent urinary troubles; since, as the urethra passes through the substance of the prostate, any abnormal development of that gland must interfere

with the calibre of the canal. If one lateral lobe is enlarged more than the other, the urethra is pushed to the opposite side, acquiring a lateral curvature, while hypertrophy of the middle lobe produces a deflection upwards, or even a valve-like closure of the outlet of the bladder. The third or middle lobe lies in the median line somewhat *behind* the lateral portions of the gland; hence, if owing to supernutrition or other pathological cause its bulk becomes increased, it pushes upwards, forming a projection into the neck of the bladder just behind the internal orifice of the urethral canal, which is therefore pushed up towards the pubes. When the bladder contracts on its contents, this projection acting as a valve shuts up, to a greater or less extent, the aperture through which the urine should pass, and the bladder, being unable to empty itself, is more and more distended by the accumulating fluid, until its muscular fibres are paralyzed; and finally the urine constantly dribbles away in small quantities. This "incontinence of retention," as it has been called, may mislead the surgeon, and prevent his comprehending the necessity for catheterization, the neglect of which may induce fatal cystitis, or rupture of the bladder from overdistention.

There is frequently great difficulty experienced in passing a catheter into the bladder in such cases, for the urethra is distorted by encroachment of the hypertrophied prostate, and the point of the instrument is arrested by striking upon the anterior surface of the middle lobe lying directly in its path. It is, however, nearly always possible to overcome this obstacle by introducing the index-finger of the disengaged hand into the rectum and strongly pushing the prostate upwards, thus lifting its middle lobe up from the urethral orifice of the bladder. If the obstruction is produced by unequal enlargement of the lateral lobes deviating the urethra to one side, the same manipulation may straighten the deflected canal. This manœuvre is very effectual, and will frequently accomplish the required object, without rendering it necessary to employ any of the so-called prostatic catheters.

As the urethra is not narrowed, but merely tortuous, and possibly very dilatatable, the catheter should be large and flexible or with an abrupt curve, so that its end may pass along the anterior surface of the urethra and over the obstruction presented by the middle lobe of the prostate. It is sometimes difficult to draw off the residual urine which lies in the lower fundus of the bladder behind the enlarged gland, and it may be necessary to raise the patient's hips to effect its complete removal.

The trouble of which this man complains is the straining and pain necessary for the expulsion of the water. This inconvenience can probably be palliated by over-dilatation of the prostatic portion of the urethral canal by means of conical flexible bougies. It must, however, be borne in mind that frequent catheterizing may produce great irritation, and that a catheter should never be allowed to remain for a length of time in the bladder.

The hypertrophied condition of the prostate gland cannot be diminished, but its temporary congestion and inflammation may be relieved by hot hip-baths, warm injections into the rectum, and rest in the horizontal position. The condition of elderly persons suffering with prostatic enlargement can be made tolerable by inducing them to avoid exposure to cold and remaining too long in the erect position; to abstain from stimulants and the use of stimulating diuretics; to refrain from indulging in sexual excitement; and to pay proper attention to the frequent and complete evacuation of the bladder, which is best effected in a prone or stooping position, so as entirely and habitually to drain the fundus.

BELLEVUE HOSPITAL, NEW YORK.

Reported by F. W. CHAPIN, M.D., House Physician.

A CASE OF ACUTE YELLOW ATROPHY OF THE LIVER.

EDWARD P., æt. 19; single; U.S.; drug-clerk; admitted December 23, 1873. Patient's father died of consumption; mother of a "flux." Patient's habits have always been very good. He denies venereal disease. Five years ago he had scarlatina. The attack was of short duration, and the recovery from it was complete. With the exception of this illness, and of an occasional cold, he was always well till two weeks ago, when he began to lose his appetite. He soon lost all relish for food, and his bowels became somewhat constipated. He took mild cathartics with relief. Still his appetite grew worse, and he weaker. During the day he had chilly sensations, which at night were replaced by slight febrile disturbance, with some sweating. He suffered no real pain anywhere, but had a sense of oppression in the epigastric and right hypochondriac regions. His food gave him no pain nor even nausea; there was simply loss of appetite. He did not notice the color of his fæces. One week ago it was noticed that the whites of his eyes were turning yellow. Shortly afterwards his skin began to assume the same hue. He gives no history of exposure to cold or moisture.

The above symptoms persisted up to date of admission, his weariness becoming greater, and his appetite remaining very poor.

On admission, the patient complains mainly of great weakness and loss of appetite, though his appetite is better than for some days past. There is marked jaundice of the skin and conjunctivæ. The urine is of a dark reddish-brown color, 1025, acid, contains bile; otherwise normal. The color of his fæces is not known. Pulse slow and tolerably full. Temperature normal. No pain, and only slight tenderness, in epigastric and hepatic regions. Lungs, heart, and spleen normal. Liver slightly enlarged.

December 24.—The patient's condition about the same. He had one discharge of clay-colored fæces last night. Case supposed to be one of catarrh of the bile-ducts. Urine high-colored, contains bile, 1022, acid; otherwise normal. Ordered pulv. aloes, gr. xii; ext. nuc. vom., gr. iss; ext. hyoscyamus, gr. vi. M. Ft. pil. no. vi. Sig.—One t. i. d.

December 27.—The jaundice persists. The patient still has no pain; complains only of weakness, and for this cause is obliged to retire at an early hour in the afternoon. Appetite is a little better. Three discharges last night of the same clay-colored passages. Urine still high-colored.

December 28.—The patient had some nausea yesterday, and has the same this morning. Ordered sodii bicarb. gr. x after each meal.

December 29.—Patient retired at an earlier hour than usual yesterday afternoon, complaining of great weakness; was aroused at 4 P.M. to receive medicine. This he did receive, but spat out immediately, and went off into a drowsy state. At 5.30 P.M. he was awakened and questioned, but his answers were incoherent. On being told to take his trousers off, he tried to do so, but seemed to forget what he was about, and got into bed with them on. The condition being considered as due probably to cholæmia, an attempt was made to give stimulants, but the patient promptly transferred the dose from his mouth to the floor, and then sank back into his drowsy condition. During the night he vomited, became delirious, and had to be tied down in bed. A hypodermic of $\mathfrak{N}^{\text{viii}}$ of Magendie's solution was given. It was some time before this seemed to take effect, but finally the patient went into a state of semicomatose.

In this condition he is found this morning: pulse 80, respiration 20, temperature $99\frac{1}{2}^{\circ}$. Jaundice much more intense. No movement of the bowels since the evening of the 27th. Ordered, as a diaphoretic and diuretic, *sps. ætheris comp.* and *liquor ammon. acetat.*, \mathfrak{zss} every hour.

P.M.—Pulse 92; temperature 99° . The above medicine was administered but once to-day, the patient refusing to swallow more. An injection brought away a small quantity of clay-colored fæces. During the injection the patient struggled deliriously, but immediately afterwards relapsed into the former state of semi-coma.

December 30, A.M.—Pulse 100; temperature 102° . Pupils slightly irregular. Pulse steadily increasing in frequency, but diminishing in force. Urine dribbles away in bed, staining the sheets yellow.

No evidences of extravasation of blood, or of hemorrhage. Liver has diminished somewhat in size. 4.30 P.M.—Pulse 140; respiration 48; temperature $105\frac{1}{2}^{\circ}$. Patient failing rapidly; cannot be roused. 6 P.M.—Tracheal râles; moaning expiration; pulse fluttering and indefinable. 8 P.M.—Patient dead.

Autopsy, eighteen hours after death.

Brain appears normal. *Heart* normal. *Lungs* congested, leathery. *Liver*.—Weight two and a half pounds; color natural; bile-ducts small and unobstructed, not bile-stained; gall-bladder contains a thin bile. *Abdomen*.—Ecchymoses in the omentum and mesentery; black fluid in the stomach and duodenum; fæces clay-colored. *Kidneys*.—small, bile-stained; epithelium fatty; markings lost.

Microscopic examination of the liver showed the liver-cells to be in a state of complete granular degeneration.

TRANSLATIONS.

ON LANGUAGE, CONSIDERED AS AN AUTOMATIC PHENOMENON, AND ON THE EXISTENCE OF A PHONO-MOTOR CENTRE.—The importance of reflex action in the animal organism is in these days universally admitted. It can no longer be limited to movements determined by the spinal cord without the intervention of the brain, but must be held to include in a general way any transformation of a centripetal impression into a centrifugal reaction. In a word, perfectly exact and incontestable reflex actions are found even in the intellectual functions, and it is the object of this paper to point out their influence in the function of language.

It is of course understood that certain reflex actions are of a very simple nature,—as, for instance, those which may be induced in the lower limbs after a section of the cord quite low down.

As we ascend in the cord, however, the higher the section is made the more complicated and co-ordinated do the various reflex acts become, until, when the cerebral lobes only are removed, even such acts as flying, swimming, and walking, according to the nature of the animal experimented upon, may be produced by excitation of the centres.

Movements brought about under these circumstances may be said to be movements of necessity. Thus, a frog deprived of the cerebral lobes, and placed in water, seems forced to make movements of swimming.

Such movements may be regarded as being influenced by nervous centres situated beneath the brain and independent of it as regards mechanism, yet which are essentially passive unless stimulated to action by the will or by external irritation. Direct action of the brain on each muscle does not usually take place, but habitual voluntary movements are probably brought about

by intermediary centres which attend, as it were, to the details.

Co-ordinative movements produced through the locomotor centres may be said to be either instinctive or acquired. An example of the first may be found in swimming with ducks, flying in the case of some birds, etc.

Of the second, we may instance such actions as placing the head under the wing during repose, since these are not performed by very young animals, but only by those older and more experienced.

Upon all such movements the will, as has been said, exercises only a general exciting and governing influence.

What is true of these general functions is also true of the language-function, for which there may be established, we think, a phono-motor centre similar to the locomotor centres above alluded to, and, like them, subject to the will. To be sure, the question is much more complex in the case of the phono-motor centre than in the case of the locomotor centres, since the nerves of impression in the former case are not, strictly speaking, sensory, and it would be difficult to demonstrate experimentally its existence and independence.

It is possible that the various reflex actions of instinct and education may be brought about by a sort of unconscious memory, which is nothing more than a frequently repeated impression which reacts on the motor cells and regulates proportionately muscular action. Having been impressed an incalculable number of times in a certain way, a given cell reacts in the same manner to an impression of a similar kind.

We believe that in language may be found all the characters of reflex acts of education. The various co-ordinating movements going to make it up are only brought about little by little, and after long education, but they are after all essentially the same as less complicated movements of co-ordination, such as those involved in walking.

In children it may be observed that the earliest efforts in language are the same among all nations, the movements being of the simplest kind. But in adults it is difficult to demonstrate automatic actions, since language with them seems constantly to be the effect of a voluntary and intellectual operation.

Occasionally, however, we may find manifest proofs of reflex action in language among adults, even in normal conditions. Take, for example, the recitation aloud of a piece of verse; how easy all goes as long as the lines follow one another in their usual order. But how difficult it is often, should a pause be made, to begin where we left off! It is necessary to go back to the beginning of the line or verse, and bring to our aid the cadence and rhythm.

How often do we find our usual expressions slipping out when they are least expected or desired! A friend salutes us with, "How d'y'e do?" and our automatic reply of "Very well" comes out, even when it expresses an untruth which we are obliged a moment later to recant.

In abnormal conditions, as aphasia, these phenomena are still more marked. You say to certain aphasics, "How d'y'e do?" they quickly reply, "Very well, thank you." "Repeat," you say to them a moment later, "the words 'Very well, thank you.'" In vain do they try: the words which were uttered automatically a moment before will not come now even at the urgent demand of the will.

Facts may be cited without difficulty to demonstrate, we believe, with considerable certainty, that there are as perfect reflex actions in the language-function as in other functions. If we bring to bear, then, in the case of this function the same laws which we know to hold good for the other nervous centres, we must admit that

there is a co-ordinating centre for language. The will does but give the order, the phono-motor centre sees to its execution.

The mechanism of the language-function may be compared to that by which a skilful musician translates his thoughts or those of some eminent composer into harmony upon the piano. So long as all his functions are properly carried on, all goes well; but should a lesion of the spinal or peripheral nerves, or of the loco-motor or the intellectual centre, occur, the performance would speedily come to a stand-still.

It is just so with loss of speech, which may be brought about by exterior organic alterations, by alterations of the phono-motor centre, or by alterations of the intellect.

Nothing seems more logical than this assimilation of acts of phonation to other movements of co-ordination; and in admitting that there exists a phono-motor centre as there exist locomotor centres we do not believe ourselves to be enunciating a new idea, but only adding to the strength of an old one by means of recent physiological facts.

We do not say, moreover, that intelligence and will do not intervene incessantly in the act of language, but we have desired to prove that in this function there is, in addition to voluntary acts, a sort of automatism which is the result of education. This automatism has all the characteristics of that which exists for other functions, characteristics which consist principally in a reflex and almost necessary succession of phenomena, which are associated by habit, and in a functional activity, only receiving from the will a general excitation.

In a word, we believe that there exists for language that which exists for walking, dancing, playing on an instrument, etc.

(From the French of M. Onimus, *Jour. de l'Anat.*)

THERMOMETRY OF THE UTERUS AND ITS DIAGNOSTIC SIGNIFICATION (Dr. Wilhelm Schlesinger: *Wiener Med. Presse*).—It has been stated that in some cases in which doubt existed as to the life or death of the fœtus, assistance was rendered by the use of the thermometer, and lately the assertion has been made that the scale of the thermometer would reveal the existence of pregnancy even in the earlier months. The two suppositions which follow give the basis of this statement: 1, that the temperature of the fœtus is higher than that of the mother; and 2, that the temperature of the pregnant uterus is higher than that of the vagina, this difference being due to an increment of heat produced and furnished by the fœtus. Schröder found a difference of 0.156° Centigrade between the temperature of the pregnant uterus and the vagina, while in similar observations of Winkel a variation of 0.13° to 0.16° Centigrade was observed.

If the fœtus dies in the uterus, not only is its influence as a source of heat done away with, but heat from the uterus is absorbed by the dead mass within. Schröder further noticed that in pregnant women the temperature of the uterus exceeded that of the axilla by 0.29° Centigrade, and in women in labor the difference amounted to 0.38° Centigrade; in the case of one woman in labor, whose child had died seventeen hours previously, there was a difference of but 0.02° Centigrade in temperature in favor of the uterus. From these results, when there was but a slight or no difference of temperature between the axilla and uterus, it would be inferred that the death of the fœtus had occurred. Schlesinger by his investigations has been led to quite different conclusions. He began his studies with the conviction that no conclusions could be drawn from the higher temperature of the uterus until it was established that it was due to pregnancy; and he endeavored to ascertain the variations in temperature between different parts of the body in women who were not pregnant. In ascertain-

ing the temperature of the uterus, thermometers were used which conformed in shape to the curve of the pelvis, and, to avoid accidents from breaking, the instruments were enclosed in a silver sheath perforated with many holes. From his numerous observations Schlesinger concludes that the temperature of the non-pregnant uterus is on an average 0.10° Centigrade higher than that of the vagina, a difference corresponding very closely with that given by Schröder and Winkel as existing in pregnancy.

These results agree fairly with the ideas which prevail at present in regard to the production of heat in the animal economy. A muscle such as the uterus could not be inactive in this respect. It must also be remembered that organs which are supposed to be sources of heat are active in this respect proportionally to their size and labor. Theoretically, therefore, the uterus when actively engaged in expelling the fœtus should show a higher temperature than the same organ when at rest and quietly containing the product of conception.

Schlesinger does not wish to be regarded as asserting the contrary, but only that these differences of temperature cannot be used in making the diagnosis of pregnancy or of the life or death of the fœtus, since they exist as well in the non-pregnant woman. W. A.

TOXIC ACTION OF OXALIC ACID AND THE OXALATES.

—At a meeting of the Société de Biologie, held January 17, 1874, M. Rabuteau presented a memoir on the toxic action of oxalic acid and the oxalates, and on the methods of their elimination from the economy. After detailing the results of several experiments with the oxalates of sodium, iron, and copper, as well as with the acid itself, administered in poisonous doses to various animals, M. R. described the method of action of this agent.

He remarked that it is impossible to see in oxalic acid a corrosive poison only: in fact, one might go further, and say that the local corrosive effects are *nothing*, the general action *everything*; and that it is this action alone which is the direct cause of death, even when this ensues shortly after the ingestion of the poison.

Death has also been observed to ensue quite rapidly, without either corrosion or any lesion of the digestive tube having been subsequently established. On the other hand, the experiments which had been detailed would show oxalate of sodium to be an energetic poison without possessing any corrosive qualities.

M. R. also drew attention to the similarity between many of the effects produced in poisoning by carbonic oxide and carbonic acid on the one hand, and oxalic acid (a chemical analogue) on the other. He also described some of the symptoms of oxaluria as coming under the general head of toxic effects of oxalic acid and oxalates, formed in the system.

Finally, he strongly deprecated the use of oxalic acid in medicine even in such form as the oxalate of iron, believing its employment to be fraught with danger.

EXTRACTUM CASTANÆ VESCÆ IN PERTUSSIS.—Dr. Ludwig Fleischmann states (*Wiener Med. Presse*) that during the summer and fall of 1873 he had numerous cases of whooping-cough under his care, and in the treatment of fourteen of these the extract of chestnut leaves was employed. The extract used was prepared after the formula suggested by Maisch. In some of his cases he obtained good results from this treatment, and thinks that it is most suitable in cases in which there is but little bronchial secretion, and in which the spasmodic character is well marked. PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 2, 1874.

EDITORIAL.

TO THE COUNCIL OF THE AMERICAN MEDICAL ASSOCIATION.

GENTLEMEN: At the last meeting of the American Medical Association, that august body very wisely created a council to determine all questions of an ethical nature, and with equal wisdom, we trust, elected you to the high trust. At a meeting of your body held May 9, at the close of the morning session of the Association, you appointed a sub-committee, consisting of Drs. N. S. Davis, R. S. Gales, and L. S. Joy nes, to report upon a revision of the Code of Ethics to a meeting of your general body to be held upon the first Tuesday of June next. On behalf of a large number of physicians, the editors of the *Philadelphia Medical Times* desire to call your attention to the subject of professional advertisement. In doing this we do not presume to offer any general rules or principles for your guidance, but we do most earnestly request that whatever restrictions bind one section of the profession shall also bind all sections; that whatever load is laid upon the profession shall press equally upon all shoulders; that there be not, as at present, a class which, by a liberal construction of the code, is allowed to advertise or to be advertised, whilst others less favored are shut off from the privilege. If, as is now the case, the use of the great modern lever, advertisement, is permitted to some and denied to others, how can you expect those who are debarred to yield other than a discontented

loyalty to your Code of Ethics and to the American Medical Association? Further, we would most respectfully submit that the debarred are the great bulk of the profession, and that loyalty discontented from just causes inevitably slides towards rebellion.

The Code of Ethics forbids physicians to advertise, and we respectfully request that the sections bearing upon this point be extended so as to apply to all alike, or else that they be stricken out and every man left to the dictates of his own reason.

As it is to-day, John Thompson, oculist, is not permitted to announce himself in the daily papers as such, and by the strict rules of the American Ophthalmological Society is not even permitted to place "oculist" upon his door-plate; whilst John Smith, physician to Round-the-Corner Dispensary, has his card as a specialist put in for him day after day, in a displayed type, which savors strongly of the patent-medicine trade. We have previously dilated upon this anomaly; to-day we have only space to denounce it as an injustice which must eventually lead to jealousy and bitterness, to bickerings and strife, or to the grievous multiplication of dispensaries, since each specialist will try to be even with his friends by founding an institution which shall advertise him within the code.

As proof of what we have said, we offer you below an exact fac-simile of an advertisement cut from the *Philadelphia Inquirer* for April 17, 1874; and we ask whether it would be possible for the personal cards of the gentlemen concerned to be put in the newspaper under more advantageous circumstances:

MEDICAL.

ORTHOPÆDIC HOSPITAL AND INFIRMARY for Nervous Diseases, No. 1701 SUMMER Street.—Service for Deformities, Tuesday, Thursday and Saturday at 12 o'clock, by Dr. MORTON, No. 1421 CHESTNUT Street, and Dr. GOODMAN, No. 1427 CHESTNUT Street.

Service for Diseases of Nervous System on Monday, Wednesday and Friday at 12 o'clock, by Dr. WEIR MITCHELL, No. 1332 WALNUT Street.

We do not blame, and we do not think the profession has at present the right to blame, the gentlemen concerned. Putting the least favorable construction upon the matter, they have simply taken advantage of an established custom for their personal advancement; putting the most favorable construction, they have only allowed their names to be used for the good of the hospital. So far as this city is concerned, the responsibility, if there be any responsibility at all, rests with the staff of that hospital which still holds the first rank among our institutions, and which originated and has persistently maintained the custom,—namely, the Pennsylvania Hospital.

We do not mean to impugn the motives of those concerned in these hospital-advertisements,—their motives are, indeed, no business of ours,—but the *fact* remains that for all practical purposes such advertisements as that here copied are personal cards, and that the specialist can have no better announcement in the daily press.

These things being so, certainly it is but proper and right that the subject should have a careful consideration by you, the highest chamber of medical ethics in the country; and we are justified in calling your attention to it.

NOTHING in this world succeeds like success. Last fall we had occasion to comment upon the exceedingly ill-advised, and meant to be damaging, attack by the *Medical and Surgical Reporter* upon *Doctor* William Pancoast, then engaged in a very bitter canvass for the position he now holds. To-day we record a very flattering editorial from the same pen, to *Professor* William Pancoast. "Consistency, thou art a jewel!"

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, MARCH 11, 1874.

THE PRESIDENT, DR. JOHN SWINBURNE, in the chair.

DR. JAMES McNAUGHTON presented a report and resolutions as chairman of a committee in regard to the death of Drs. J. F. Townsend and Peter Van Buren, former members of the Society.

Dr. S. H. FREEMAN also made a report relative to the death of Dr. J. H. Lasher, a junior member of the Society. Both reports were adopted and ordered entered on the minutes.

The names of Dr. R. F. Burton, of Knowersville, and Dr. George W. Papen, of this city, were proposed for membership.

SENILE HYPERTROPHY OF THE PROSTATE.

Dr. JAMES S. BAILEY read an interesting paper on this subject, of which the following is an abstract. He said that writers differ materially as to what constitutes hypertrophy. The whole subject seems to be but little understood. The adult prostate is usually described as being about the size of a chestnut, and as ranging from four to six drachms in weight. According to Sir Henry Thompson, the average weight may be estimated at from four and a half to four and three-fourths drachms. Dr. Messer, in one hundred dissections of prostates from subjects about 60 years of age, gave four drachms and fifty-seven grains as an average weight.

The measurements as given by Sir Henry Thompson also nearly correspond with the researches of Gross, Hodgson, Senn, and Deschamps: viz., from the base to the apex between 1.3 inches and 1.8 inches, transverse measurement 1.75 inches, thickness .7 inch.

Hypertrophy is common in men advanced to 50 or 60 years of age, though it does not always occur.

The enlargement may be caused by the tissue increasing in its formation, and not by inflammatory action. A prostate weighing seven drachms is considered hypertrophied. This condition is indicated by a fulness of the parts.

The result of enlargement is to obstruct the flow of urine, although in some instances urine is voided involuntarily.

The enlargement of the median portion shortens the curve; when one lateral lobe is unduly enlarged it gives a lateral curve to the course of the urethra, and *vice versa*. The symptoms are not always at once discerned, but a period of several years may intervene before micturition is obstructed.

One of the earliest symptoms is a diminution in the force of the stream of urine, and when an effort is made to expel it a hesitation to flow is experienced. The size of the stream may not be diminished, but the force cannot be much augmented by a strong effort. In some cases additional straining to void urine increases the difficulty. The desire to urinate is increased, and the ordinary satisfaction after emptying the bladder is not experienced. There is also an uneasiness experienced about the rectum and perineum. The urethra also sympathizes, as is manifested by a smarting soreness which extends to the glans penis. When the bladder is distended above the pubes there is dulness on percussion, and a tumor may be felt. In the latter stages the patient is compelled to lean forward and support his head against some object in order to make the urethro-vesical orifice the most dependent portion of the bladder.

The kidneys become embarrassed in their functions, and the urine is backed up through the ureters, and uræmic poisoning is induced, which results fatally.

The urine changes in appearance; it becomes tenacious and stringy from mucous deposits, and is often mixed with pus and the triple phosphates. The odor is fetid and ammoniacal. The chemical reaction is at first neutral, afterwards alkaline, with high specific gravity.

Microscopically may be found blood- and pus-corpuscles and epithelium. Among the crystals are seen the triple phosphates of magnesia and ammonia, besides granular matter and crystals of uric acid and oxalates. Albumen is generally absent, unless introduced by blood or pus, or unless the kidneys are invaded by disease.

The causes are obscure. The following are the most prominent: habitual constipation, horseback-riding, old age, irritation from vesical calculus, stimulating diuretics, intemperance, cold, gout, rheumatism, external violence, use of catheter, chronic diarrhœa, repeated attacks of gonorrhœa, etc.

In youth the prostate becomes enlarged by interstitial plastic effusion, the result of inflammatory action. In age there is an unnatural development of the gland.

The treatment consists in relieving congestion and pain, and in quieting the disposition to pass water. Relieve the bladder by free exit of urine. Hot hip-baths are always acceptable and beneficial in every stage. Opium is also indicated. If these remedies do not relieve, then resort to the catheter without delay.

Dr. Bailey much preferred a silver catheter,—a No. 10, and 14 inches long. Its curve should comprise one-fourth of a circle, measuring from four to five and a half inches in diameter.

The largest instrument the urethra will admit is the best, and less liable to make a false passage.

Reference was made to Dr. Squire's vertebrated prostatic catheter, but, as the doctor had not had experience with it, he referred it to other members of the Society to speak of its merits. Three cases were given to illustrate the paper, as follows:

Case I.—William Smith, æt. 72, machinist, took cold, and had difficulty in urinating. July 7 he failed entirely to micturate, and the catheter was introduced with difficulty. About three pints of dark, bloody urine escaped, which only partially relieved the pain, which he described as being across the loins and shooting down the thighs. It was with difficulty that he could get in or out of bed, or change his position while in the recumbent posture.

His urine remained tinged with dark blood until the 22d of July, when a failure was made to empty his bladder, owing to the eyes of the catheter (which were small) filling with dark decomposed fetid blood.

Dr. Swinburne was then consulted, and by the use of a No. 11 silver catheter with large eyes the thick, bloody urine was evacuated, and then by means of a fountain-syringe attached to the catheter the bladder was washed out alternately with warm and cold water. Upon the next catheterization the urethra seemed shortened more than an inch, and the urine escaped clear, with occasionally a coagulum of blood. About this time he manifested symptoms of uræmic poisoning, was delirious, and had spasms. After washing out the bladder twice each day these symptoms improved for one week; at the expiration of which time his appetite began to fail, and he died August 3.

Necropsy, twenty-four hours after death. Rigor mortis marked. Abdomen: liver somewhat enlarged, edges rounded; ductus communis choledochus occluded; gall-bladder small, containing a few calculi and a drachm of mucus; pancreas thickened and quite hard on section, normal in appearance; spleen healthy; right kidney healthy; left kidney—the supra-renal capsule enlarged to the size of the kidney itself, presenting on section a granular look, and of a pale color, had the appearance of a morbid growth; kidney itself disorganized, with only two or three pyramids remaining; ureters not affected; bladder-walls considerably thickened; half an inch from the mouth of the urethra a longitudinal elevation, an inch or more high, composed of the hypertrophied third lobe of the prostate gland, so situated as to fall as a valve across the mouth of the urethra; it was congested, was soft and rather friable, and contained two or three perforations; prostate enlarged to two inches antero-posterior diameter, and a little more than two inches in the transverse diameter; urethra normal throughout, except at the external orifice, where there was stricture with dense tissue; alimentary canal normal; thorax not examined.

The urine was examined on July 11, and found alkaline, of low specific gravity, containing an abundance of albumen and blood-globules on microscopic examination. July 25, it was again examined, and found strongly alkaline and of ammoniacal odor, with a slight amount of albumen, and depositing triple phosphates and phosphate of lime.

Case II.—J. E., attorney, æt. 68. Health always good, but for the last few years has had some difficulty in micturition. Has never required medical aid until May 7, when he suffered from retention of urine, which was relieved by catheterization. His urine dribbled away from the distended bladder without relief, until May 11, when Dr. Hun was called. His abdomen was tympanitic; he had hiccough, with rapid and feeble pulse. The left leg was cedematous, and mottled up to the middle of the thigh. No induration could be felt in the course of the femoral artery. Through the aid of the catheter one quart of bloody urine was drawn off, followed by an ounce of clear blood, which afforded great relief.

May 12.—No hiccough, and less distress. The catheter was introduced, but no urine followed when withdrawn; the eyes were obstructed by clots of blood. An injection was then used, of warm water, to clear the eyes of the catheter. Up to May 18 the urine was

drawn off three times per day, and was much clearer. The patient seemed bright and better. The œdema of the leg continued, but was soft, and the superficial veins were more marked, and were everywhere visible.

He died May 21.

Necropsy, twenty-four hours after death.—Head not examined. Thoracic and abdominal viscera normal, except the bladder, which was distended with bloody urine and some firm clots of blood. All three lobes of the prostate were much enlarged, and there was some ulceration at the upper and posterior portion of the middle or third lobe, from which the hemorrhage must have taken place.

Case III. has unusual interest, from the circumstance that the subject was the eminent surgeon Dr. Alden March. He had suffered many years from irritable bladder and hypertrophied prostate. Any unusual excitement, such as the performance of a hazardous surgical operation, was sure to increase this disturbance.

More than fifteen years ago, while travelling in Switzerland, he met with an accident while descending Mount Righi,—slipping on a rock and striking the lower part of the abdomen on a projecting point. The injury was severe, and confined him to his room in Lucerne several days, with local symptoms. Before this time he provided himself with a urinal, and, when travelling, kept it at hand night and day. Some time later he met with another accident in running up the steps of a railroad depot: tripping on a step, he struck heavily on the edge of the platform. He suffered very much at the time, and was exceedingly alarmed. Speaking of the accident, he said, "I thought that I had killed myself: that I had ruptured my bladder." He never entirely recovered from this injury.

A few weeks before his death he made the journey to New Orleans to attend a meeting of the American Medical Association. On his way home he travelled night and day continually, which undoubtedly did him much harm, although upon his return he resumed his business and attended to distant calls.

After a fatiguing ride through rain and cold in the country, he returned home quite ill, with fever and a constant desire to void urine. He used cathartics, followed by opium, together with warm baths, which afforded him relief for the time being, and from this attack he partially recovered, and in a few days at the hospital performed a difficult operation.

From this time his health broke down, and his decline was quite apparent; he was not enabled to do much more practice.

On June 6 he attended church, and remained during the service, but was in great distress from the old trouble, and at the close of the service he rushed from his seat to the closet adjoining the lecture-room and partially emptied his bladder. He remarked to a friend, "I never suffered so much pain in all my life; I could not have borne it another minute."

From this time his professional labor ceased, and he sought retirement at the house of his son-in-law, to avoid the annoyance of consultations.

The urine dribbled away an ounce or two at a time, and no effort was made to introduce the catheter until some time after the 6th of June, some eleven days before his death, as he died upon the 17th of the same month, aged 74 years.

When an effort was made to introduce the catheter, it was passed up its whole length without entering the bladder. Blood coagulated in the catheter, no urine passed through it, but some passed external to it, and some followed its withdrawal.

Again, a few days before his death, another effort was made, when the patient was anæsthetized; the catheter was again passed its full length, when it met a firm, resisting body, and again the effort was unsuccessful.

About this time symptoms of uræmic poisoning commenced, and finally hiccough, delirium, and stupor set in, and the great surgeon closed his eyes in death.

Autopsy.—Body well nourished. Palpation of the abdomen revealed the presence of a hard, globular tumor occupying the hypogastrium.

The abdomen was laid open by a crucial incision. The abdominal walls contained a considerable layer of adipose tissue, and the muscles presented a healthy color.

Upon turning back the flap, the bladder was found to be distended, and occupied the hypogastric region from the pubes to the umbilicus, the fundus being a little to the left of the median line. There were some old adhesions between the omental and vesical peritoneum. A trocar was introduced into the anterior portion of the bladder, and rather more than a quart of slightly turbid urine was drawn off. A longitudinal incision having been made along its anterior walls, the internal surface of the bladder was brought into view, and was found to present the reticulated appearance usually met with in cases where obstruction has been offered to the free flow of urine, but there was no abnormal thickening of the walls of the organ. A deep depression existed behind the prostate, owing to the enormous hypertrophy of this gland. A catheter was now introduced through the urethra into the bladder without difficulty. The bladder, with the prostate and a part of the membranous portion of the urethra, was removed from the body in a mass, and the prostatic enlargement was now well shown, and appeared mainly due to hypertrophy of the two lateral lobes.

A catheter was passed from the bladder into the urethra until it emerged externally, and then the incision already made along the anterior wall of the bladder was prolonged downward through the upper wall of the urethra, the catheter serving as a guide for the knife. This having been done, it was found that, although the prostatic portion of the urethra was laid open, yet the membranous portion remained uncut. It was also observed that the connective tissue lying anterior to the prostate gland and neck of the bladder was stained and infiltrated with blood, although there was no evidence of any urinary infiltration. The middle lobe of the prostate was enlarged in such a manner as to form a cul-de-sac just below the vesical orifice of the urethra. The kidneys were rather larger than usual, and contained several cysts filled with a straw-colored fluid, which cysts were situated in the cortical substance and projected beyond the surface of the organ. The pelves of both kidneys were enlarged, but whatever fluid they may have contained escaped unnoticed when the ureters were divided. The renal tissue appeared somewhat congested, but was otherwise normal, and subsequent microscopic examination showed no alteration of the Malpighian bodies or uriniferous tubules. The other abdominal viscera presented nothing abnormal.

The head and thorax were not examined.

Dr. A. VANDERVEER presented pathological specimens of *enlarged prostate*, and gave the history as follows:

W. H. J., æt. 66, good habits, shoemaker, health usually good. December, 1873, noticed some trouble in passing his urine, with a constant desire, and without the ordinary satisfaction after doing so. On the 12th he could not pass his water. The doctor was then consulted. He had but little pain; abdominal tumor well marked, reaching up to the umbilicus. An attempt had been made during the day to pass a gum-elastic catheter, but no urine followed its use. After injecting the urethra with warm oil, Dr. Vanderveer passed, with ease, a No. 12 silver catheter, and drew off about two quarts of urine. The use of the catheter was continued for two weeks, twice daily. After this, and for the next

twelve days, he voided urine with comparative ease. At this time he was attacked with acute bronchitis, and it became necessary to employ the catheter two or three times daily to relieve the bladder.

A thorough tonic course of treatment was adopted, but he gradually sank, and died February 10, 1874. A week previous to death, a trace of albumen could be found in his urine, but no casts.

Post-mortem, twelve hours after death.—Head not examined. Organs of the thorax in a healthy condition; abdominal organs healthy, excepting kidneys and bladder.

The kidneys were very much enlarged; capsules adherent, and glandular structure much congested. The bladder contained a pint of ammoniacal urine; walls thickened, and mucous coat covered with arched and crossed columns of tissue.

The middle lobe of the prostate gland was enlarged in such a manner upward and forward that when the bladder became at all full, this hypertrophied tissue acted as a valve, preventing the exit of urine, and accounting for his inability to empty his bladder.

Dr. VANDERVEER further remarked that he had had better success in relieving retention of urine due to hypertrophied prostate by the use of the olive-pointed catheter, and then referred to an idea gained from Dr. Gourlay, of New York, who had obtained it from Sir Henry Thompson. The gum-elastic catheter should be immersed in warm water first, and the desired curve given it, when it should be immersed in cold water, which would harden it, when it can be introduced, and by the time it meets with the obstruction the point softens and glides over it.

Dr. JAMES MCNAUGHTON thought more depended on the practised hand of the operator than on the instruments; there was a great deal in tact. He expressed his appreciation of Dr. Bailey's paper, and remarked that his views entirely corresponded with his own experience.

THE PRESIDENT spoke of the peculiarity of Dr. Bailey's case and of one other he had seen with Dr. Vedder, of Schenectady, in regard to the bladder filling up with blood which was dark and very fetid; he had never witnessed the like before.

Dr. THOMAS BECKETT mentioned a case having recently come under his observation, of a boy with a full bladder having been kicked by a horse. The next day no urine could be obtained until a stream of water was injected, which had the effect of breaking up the clot which had formed in the bladder.

The discussion was further continued by Dr. S. H. FREEMAN and others, after which the Society adjourned.

REVIEWS AND BOOK NOTICES.

FIFTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS. Boston, January, 1874. Wright & Potter, State Printers.

The Fifth Annual Report of the Massachusetts State Board of Health lies on the table before us, and, while we cannot afford space to analyze it, we have both the will and the ability to commend it. There are without doubt some papers in it which it would require the wisdom of Solomon to discover the usefulness of, but on the whole the volume is a decided success. From it we learn that the expenses of the board for the year have been only \$4347.75.—a sum which we judge is not more than the annual levy laid by the patriot Benjamin upon his custom-house appointees for the purpose of influencing the free and independent voters of the Bay State. Surely the taxpayers cannot complain. Among the

various papers contained in the five hundred and fifty pages of this goodly volume we have been especially attracted by one on school hygiene, by Dr. Fred. Winsor, of Winchester. Circulars containing a number of questions were sent by him to various persons, and replies were received from one hundred and sixty individuals; one hundred and fifteen of whom are physicians, and twenty teachers or school superintendents. As bearing upon the question of "sex in education," we notice that seven-tenths of the correspondents answer that girls are more liable than boys to be injured in health by schooling, and eighty-seven one-hundredths state that this liability greatly increases at puberty. Dr. Winsor further asserts that seven-eighths of the female teachers suffer from the present system, and in a very delicate manner proposes that the school system should be so modified as to allow absence or mitigation of study during menstruation; at least this we believe to be his meaning, for he sacrifices perspicuity to modesty. As the boys would soon probe any such change to the bottom, we can well imagine the sly winks and hints, and even the broad jokes, which Sallie or Katie being "off lessons this week" would give rise to.

A TREATISE ON PHARMACY, designed as a Text-Book for the Student and as a Guide for the Physician and Pharmacist. By EDWARD PARRISH. Fourth Edition, enlarged and thoroughly revised, by THOMAS S. WIEGAND. Philadelphia, H. C. Lea, 1874.

"Parrish's Pharmacy" is a book too well known to need any notice from us. Its aims and its successes, its strivings and its failures, have been seen of all men, and our readers know as well as we do that its chief value is to the pharmacist, and that it appeals almost solely to those members of our profession whose circumstances of practice force them to attend to pharmacy. Mr. Wiegand appears to have done his work carefully and conscientiously. Indeed, he has rewritten much of the first part of the book, and altered and added to other portions of it, so that the size of the volume has been increased about one hundred and fifty pages. To those who need a treatise on pharmacy we can commend the work, as it now stands, as the most complete and satisfactory in the language.

GLEANINGS FROM OUR EXCHANGES.

CINCHONIDINE AS A FEBRIFUGE.—An Indian journal, published in the centre of the tea-districts, has the following observations:

The report of the Madras Commission, dated 15th June, 1868, sums up the result as follows: Most of the medical officers employed in using the alkaloids seem fully impressed with the belief that they are equally or very nearly as efficacious as ordinary quinine, and the mass of information furnished in the tabular reports published proves that such belief is well founded. It has been shown that the total number of fevers treated by the new alkaloids and chemically-pure quinine is 2572, of which only twenty-seven are stated to have failed, and of these no less than eleven were at Labuan. The failures, it will be observed, are but a little in excess of one per cent. of the aggregate number treated, which is certainly a most favorable result, especially when it is known that many of the patients are saturated with malaria and ill fed, as evidenced by their enlarged spleens and emaciated condition. In regard to the relative effects of the three new alkaloids, and with them chemically-pure sulphate of quinine, the evidence derived from their use shows that, with the exception of sulphate of cinchonine, as already stated, they in a remarkable degree so closely resemble each

other in therapeutical and physiological actions as to render distinctive description of little or no practical utility. In reviewing the whole of the operations for testing the therapeutical effects of the cinchona alkaloids, the result confirms generally the favorable opinion expressed by the Commission last year, and likewise conclusively establishes beyond doubt that ordinary sulphate of quinine and sulphate of quinine possess equal febrifuge power; that sulphate of cinchonidine is only slightly less efficacious; and that sulphate of cinchonine, though considerably inferior to the other alkaloids, is, notwithstanding, a valuable remedial agent in fever. . . . Dr. Jackson's experiments extended over no less than 564 cases. "These alkaloids are all," he says, "possessed of highly antiperiodic properties in malarious fever. They were given in the above number of cases without one fatal termination. It is true that the fever, though generally prevalent among the prisoners, was of a very mild type; the fact, however, remains that the average duration of treatment was about six days" (here Dr. Jackson omits to reckon the large numbers cured by single doses), "and such a result can only be accounted for by following the very marked specific effects of the alkaloids administered. I much doubt if such a result could be obtained by the administration of any other of the well-known antiperiodics, always excepting the *facile princeps*, sulphate of quinine itself." Dr. Fogo writes: "In small doses all the alkaloids produce the same therapeutical effects,—that is, as tonics, antiperiodics, and antineuralgics. Hypodermically and internally they have proved successful. In large doses they are all equally energetic, and produce their effects rapidly. They have been successfully used as antiperiodics and febrifuges. We have now three alkaloids in addition to quinine, all of great power. Quinine appears to be the most active and certain in its effects, and from long-established reputation it is not likely to be superseded by any of the other alkaloids, at least not until they become more known. *In many constitutional peculiarities where quinine cannot be borne, these alkaloids will be found good substitutes, and they can all be substituted for each other.*" "In conclusion," says Dr. Bensley, "I beg to say that I look upon quinidine, cinchonine, and cinchonidine as valuable additions to our small stock of antiperiodics, worthy of as much, if not more, confidence than quinine has obtained; one of them, quinidine, having proved itself more successful than quinine, and another, cinchonidine, having secured for itself a position perhaps the most exalted of all, inasmuch as it has afforded us a good febrifuge for cases which from peculiar susceptibilities were opposed to the administration of quinine. So much convinced am I now on this point, that I should feel quite content were I for the future left to deal with all my fever-cases with no other preparation than quinidine and cinchonidine." Dr. Jackson, of Meerut, thus concludes his report: "Of the three alkaloids I am of opinion, and my native doctors are the same, that cinchonidine is by far the most valuable." Dr. Fogo, also at Meerut, observes, "Cinchonidine is in many respects as energetic as the others, and one thing greatly in its favor is that the physiological effects it produces are not so powerfully manifested, and pass off very quickly." Dr. Staples (19th Foot), of Nowshera, says, "It was not found in intermittent fever so efficacious as quinidine, but, like that drug, was a useful tonic in convalescence." Dr. Bensley, of Midnapore, whose therapeutical report treats mainly, and his statistics entirely, of the collective value of the alkaloids, makes the following distinctive remarks of cinchonidine: "It is admirably suited to those cases requiring a tonic or febrifuge, in which at the same time there is a great tendency to diarrhoea, or diarrhoea already exists. Among the cases will be found two in

which quinine produced irritation of the bowels, but cinchonidine was well borne. None the less valuable is it, in consequence of the mildness of its influence on the nervous system, in those cases which, from peculiarity of constitution, are ill able to bear the more powerful alkaloids." Dr. Bensley concludes by saying, "I have used cinchonidine extensively in the fevers of children, on account of its mildness, and because it is less liable to produce head- and bowel-disturbance than other alkaloids. Upwards of thirty of my cases were children varying in age from one to nine years. I have such confidence in it that it is now the only preparation I prescribe for children."—*The Journal of Applied Science*.

THE INFECTION OF SMALLPOX.—Dr. Zuelzer, of Berlin, has just published the results of some experiments which he has made on monkeys (*cercopithecus*) with variolous matter. About a drachm of blood from a severe case of smallpox, and about the same quantity of pus from the mature pustules of another case, were made into small balls with bread-crumbs and given to two monkeys. Both remained well. Ten days later, the hair was cut, without injuring the skin, from a part of the back of one of these monkeys. A piece of charpie charged with variolous pus was laid on the spot, covered with a watch-glass, and secured by strips of adhesive plaster, till the end of three hours, when it was removed and the place washed. No infection followed. Twelve days later, some blood from a severe case of variola was inoculated into several parts of the back and inner surface of one of the thighs of the same animal. The blood used contained a very large number of globular bacteria. On the sixth day after the inoculation, the temperature began to rise, the normal in the rectum being in the morning about 100.4° Fahr., and in the evening 102.5°; and on the seventh day it was 105.5° to 106.4°. The animal lost its appetite, but this returned on the ninth day. Red spots appeared in great abundance on the rump, and single ones on the back, on the inner surface of the thigh, and on the mucous membrane of the fauces; they soon developed into papules, some of which became flat pustules, which soon burst. To test the possibility of conveying infection through the breath, a quantity of desquamated epidermis from smallpox patients, and small pieces of linen impregnated with their blood and pus, were used. These were placed in several small gauze bags in a wooden cage, which was often shaken. A small wire basket filled with the same materials was also given to an animal to play with. It sickened on the fifteenth day, presenting the same symptoms as in the former case. Dr. Zuelzer arrives at the following conclusions: 1. The blood of variolous patients is infectious. 2. Infection does not take place through the digestive apparatus, nor, probably, through the sound skin. 3. Infection takes place through inoculation, and also through the respired air, when this is sufficiently charged with the poison.—*British Medical Journal*.

CHLORAL HYDRATE SUCCESSFULLY USED IN TETANUS.—Dr. Coryllos, of Patras, in Greece, published a case of this kind in the *Allgem. Wiener Med. Zeit.*, No. 2, 1873, and now the same author records two similar cases, one under his own care, and the other treated by Dr. Basilin. The latter case relates to a woman of forty, who had wounded her finger with a splinter, which she removed herself. Tetanus occurred one month after the accident, and she had more than ten general attacks in the twenty-four hours. Sixteen days after the first tetanic symptoms the patient removed from the wound a bit of splinter, the size of a pea, which had been left in it unobserved. The usual narcotics having failed, chloral was tried, and succeeded. Altogether three ounces and a half were taken in twenty days.

In Dr. Coryllos' case a man of forty had his left temple wounded by a pointed piece of reed. Tetanus supervened, and here, again, a portion of the foreign body was removed twelve days after the accident. He had at first fifteen-grain doses of chloral, and improved much upon them. But the tetanus recurred with renewed severity, and the chloral was pushed as far as one hundred and twenty grains per diem. The patient completely recovered, and had taken, in about thirty days, six ounces of chloral.

PUTRID POISONS.—Dr. Kehrer, after detailing (*Archiv für Experiment. Patholog. und Therap.*, 1874) a number of experiments in which various fluids of a putrid nature were injected into animals, gives the following conclusions: 1, the putrid fluid is not soluble in water, but remains in it in a state of suspension; 2, after exposure to heat (boiling) for fifteen to twenty minutes it loses its power; 3, cold has no influence; 4, at the point of injection there arises, according to the size of the dose, more or less diffuse inflammation, followed by acute fever, and frequently gastric catarrh; 5, in rabbits doses of .8 to 1.6 centimetres of putrid fluid frequently cause death; larger doses do so invariably. Occasionally this ensues within one or two days, but sometimes only after suppuration prolonged to fourteen days.

On cutting open animals which have been killed quickly, a strong, putrid odor is very perceptible, particularly at the point of injection.

The heart and vessels are full of thick blood. Local and surrounding tumefaction of the gastro-intestinal mucous membrane is found, together with watery or slimy contents of the intestinal tract.

TEPID BATHS IN THORACIC AFFECTIONS.—Touplet (*Arch. Gén. de Méd.*) gives the results of his observations as to the influence of baths of a temperature of about three [C.] degrees less than that of the body (bains tièdes) upon patients with maladies of the chest, more particularly those affected with phthisis. He placed patients with this disease in baths of the temperature stated, and allowed them to remain immersed for from twenty to forty-five minutes. He found that after the bath the frequency of the pulse and the temperature were less than before, and that this reduction was more marked in those cases in which the frequency of the pulse and the temperature had previously been much above the normal figures. Good effects were also manifested in reducing the night-sweats and nervous excitement, and in increasing the appetite.

THE ACTIVE AGENT OF ERGOT.—Dr. A. Wernich has recently made some investigations in the Berlin Institute, in regard to the active principle of ergot. He finds that the watery extract is far more powerful than either the alcoholic or the ethereal extract. The watery extract, when purified by alcohol and ether, forms a mucous or slimy mass which cannot be dried. The active agent appears to be of the nature of an acid soluble in alcohol when pure, but insoluble when in combination with bases.—*London Lancet*.

DR. BERKART requests us to state that he lately injected weak solutions of carbolic acid through the thoracic parietes into the lung in a very bad case of phthisis at the Tottenham Hospital. The effect produced was most striking. In a few minutes after the operation, which is said to be quite painless, the patient was "sitting up in bed comfortably, eating an egg." In Germany, Koch and Mosler have recently published observations on this subject, but Dr. Berkart informs us that he had suggested the idea as far back as 1872.—*London Lancet*, March 28, 1874.

MISCELLANY.

HYRTL'S RESIGNATION.—On the 16th of March of this year Prof. Hyrtl withdrew from the Chair of Anatomy in the University of Vienna, to the reputation of which he has by his labors contributed so much. Some years ago Hyrtl expressed a desire to free himself from the arduous duties which devolved upon him as professor, and, although he had repeated this desire from time to time, it was not realized until the present year.

Joseph Hyrtl was born in Hungary, in the year 1811, and in his tenth year came to Vienna, where, upon the completion of his studies in the gymnasium, he in 1830 entered the medical department of the University as a student. Even at that time his leaning to anatomical studies was marked, and it served to attract the notice of Joseph Czermak, who was at that time Professor of Physiology. He received his degree of Doctor in Medicine in 1835, and in 1837 was made Professor of Anatomy in Prague, whence, in 1845, he was transferred to the same chair in Vienna. Notwithstanding all the honor and reverence in which he was held by his numerous students, as well as by those who were more advanced in academical rank, Hyrtl was not satisfied with the position which he had at Vienna, and frequently in his lectures alluded to the time he had spent in Prague as the happiest period of his life. His lecture-room was not large enough to accommodate the students who flocked to hear him, and from this he derived a fresh cause of complaint, thinking that the hesitation of the authorities of the University to build a new amphitheatre for the use of the anatomical chair arose from a personal jealousy, and not, as was really the case, from causes beyond their control.

From this and other causes of misunderstanding, for some years past he has taken no part in the proceedings of some of the most prominent medical societies of the Austrian capital.

His withdrawal from his chair was celebrated by deputations from the various societies of the students and medical men, as well as from the Faculty of the University. These visited him at his residence, and expressed their regret and their sense of the loss which the school would suffer by his resignation.

On Monday, the 16th of March, his lecture-room was crowded, as well as the court-yard and passages of the building in which it is situated, and upon his appearance at the table in a coat and without the well-known mantle which he wore at his lecture, Hyrtl was greeted with tumultuous applause, and in a voice broken with emotion he for the last time addressed his class, bidding them adieu, and telling them that his career as an anatomical teacher was over. Hyrtl's voice was scarcely audible, and at the end of his oration, with tears in his eyes, he leaned upon his friend and assistant Friedlowsky, who was quite as much moved as himself. Other orations were made at this time, and in the evening the students had a celebration at one of the large public halls, conducted according to the rules which have for so long a time held sway among them.

Three days later, on the anniversary of Hyrtl's patron saint, Prof. Ritter von Oppolzer—his former teacher, and the old friend of his father—presented him with a wreath of silver laurel leaves, and on the same day a deputation from the municipal authorities of the city offered to him the honorary citizenship of Vienna.

DEAR, BUT NOT GOOD.—The *Times*, of India, has a story how the Dewan of the Guicowar of Baroda, being ill, sent for a doctor, who desired the Dewan to send him next day a bottle of his urine for examination. The doctor used the Hindustani term *karoova* to express urine, and this term was not understood by the patient; but, being desirous of obeying the doctor and sending him what he wanted, the Dewan rummaged the whole town for *karoova*. At last a crafty fellow from Delhi offered to supply it, and sent a bottle, for which he charged fifty rupees. The Dewan tasted the liquid, and pronounced it not nice. However, next morning he sent the bottle to the doctor, saying that it had cost fifty rupees, and a great deal of trouble, and after all, was not nice! The doctor "smole a smile," and then explained the real meaning of *karoova* to the unhappy Dewan.—*Med. Times and Gazette*, February 21.

THE INK OF THE ANCIENTS.—In a letter from Mr. Joseph Ellis, of Brighton, addressed to the *Society of Arts Journal*, he states that in making a solution of shellac with borax in water, and adding a suitable proportion of pure lampblack, an ink is produced which is indestructible by time or chemical agents, and which on drying will produce a polished surface, as with the ink found on Egyptian papyrus. He made ink in the way described, and proved, if not its identity with that of ancient Egypt, yet the correctness of the formula, which was given him by the late Mr. Hackett.—*Druggist's Circular*.

HAY-MITES.—Some time ago a large number of horses died at Nordheim, Germany, from inflammation of the intestines, the true cause not at first being known. At last it was assigned to the hay, in which, upon close examination, an immense number of microscopic animalcula were found. They belonged to the genus *Acarus fenarius*, to which genus the mites living on dry fruit and in cheese also belong. In times of horse-disease it might, therefore, be proper microscopically to examine hay and straw, since even the best fodder, if stored in a damp place, is very likely to be infested by those and other parasites.—*Journal of Applied Chemistry*.

MEDICAL LEGISLATION.—The Kentucky legislature has lately passed a law requiring all who prescribe for the sick either to be regularly graduated by a duly chartered medical college, or else to obtain proper credentials from a State Board of Medical Examiners, of which there is one in each judicial district of the State. Every candidate for practice in North Carolina must pass a satisfactory examination before the Board of Medical Examiners of that State before he can obtain license to practise.

THE *Clinic* reports the death of Dr. H. G. McAllister, of Cincinnati, produced by taking a drachm of chloral and a half-ounce of bromide of potassium. The stupor which ensued was mistaken by his wife for sleep, and the doctor was found by her dead in his bed the next morning.

DR. SHARPEY, the distinguished professor of physiology at University College, is to be placed on the Civil List for a pension of £150 per annum.

ALBERT P. BROWN recommends *pyralin* as an artificial digestant, and gives a method of preparing it.—*American Journal of Pharmacy*, p. 186, 1874, vol. iv.

JOULIN, editor of the *Paris Gazette de Joulin* (obstetrical), died suddenly in his cabinet March 18, 1874, at the age of fifty-three.

IN Paris, thirty-seven streets, according to a Parisian cotemporary, are named after medical men.

GOSSELIN was the successful candidate for the vacant seat of Nélaton in the Paris Academy of Sciences.

NOTES AND QUERIES.

MARSHALLTOWN, IOWA, April 9, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

MR. EDITOR,—I desire to make some remarks in reply to the editorial which appeared in the *Philadelphia Medical Times*, entitled "The Annual Overflow." The first thing to which I wish to call attention is that the author of "The Annual Overflow" need entertain no fears of the profession not growing in power as well as number; certainly no man who for a moment stopped to reflect upon the discoveries and improvements which are almost daily added to the scientific and the art department of the profession would say, "We fear." The comparison of the medical profession to that of a chain lengthened by links of imperfect workmanship is, I think, rather a poor one. I admit that men miss their calling in some instances, and weak links are interspersed here and there, but those here-and-there weak links may be found throughout the entire chain, save those which time has rusted out. There is little doubt but that fewer weak links will be found in the portion of the chain which has been last constructed than there would be in the portion which was constructed years ago. It is not indisputable that the profession loses influence or lessens with age, but, on the contrary, we have reason to believe it to be gaining. I think if the author of "The Annual Overflow" would take time to call upon some of the boarding-house-keepers and the medical schools of Philadelphia, he would find in most instances that medical students of the present day, as a general rule, are more refined than they were years ago. This does not look as though there were any reason why physicians should lose influence. Are quacks and impostors turned out only from the later graduates? No; the proportion of such to the regular practitioners is no greater than it was fifty years ago. The incident which is given as an example—Mr. Smith—is unfair. This particular gentleman has missed his calling; but because he was a cooper was not the reason why he did not make a doctor; there are plenty of coopers who in three years would make good doctors; there are also plenty of men who have had all the facilities of acquiring a preliminary education and a medical one, who are and ever will be as little competent to practise medicine as was Dr. Smith. Were not some of our best men in the profession mechanics in their early days? In regard to the doctor whose key-note of the English of his prescription was "stummik," I would simply say that that was no reason why he might not have been a competent practitioner of medicine. I have but little doubt that the English was not his native language. Suppose a farmer's son or a mechanic's son is dubbed a medical student after he enters the office of some respectable physician, has he not a right so to be dubbed? for he may yet excel his fellow-student, who has, perhaps, spent most of his time within college walls, but the latter, possibly having little brain, or brain of poor quality, and consequently no judgment or common sense, makes no doctor. Who deserves to be called a medical student?—the farmer's son, who, in the eyes of the author of "The Annual Overflow," is ignorant, and yet becomes distinguished, or the one

who has scarcely seen the sun shine through other than college windows? The farmer's son, I say. Honor to whom honor is due.

Yours, etc.,
M.D.

[We have always felt very sad and depressed concerning human nature and its future when, having made a joke, we have been called upon to explain it. How much sadder and more depressed when, having tried to write simple and plain Saxon concerning a very serious subject, we have failed to make ourselves understood! Certainly, M.D.—if, unlike Dr. Smith, he has not missed his calling—has missed our point. We have nothing to say against capable and studious mechanics, farmers' sons, or hod-carriers rising by three years' hard study into the profession. We distinctly stated that they might do so. We did, and do, most earnestly object to their loafing into it in one year, which is all that our system of education really requires.

We do not care to defend the figures and the literary features of our editorials; they must stand or fall by their own merit. We would not have replied at all to our correspondent had not the importance of the matter demanded some comments. The fact that M.D. states that Dr. Smith is an unfair example, proves the truth of what we have just said in regard to his misunderstanding us. Dr. Smith is, we believe, an unfair example of an average American medical graduate. But a hole large enough to let one big rat through will suffice for the passage of an army of the vermin. And Dr. Smith's case proved our point as conclusively as if we had filled twenty columns of the *Times* with instances. The point was that graduation at a medical college of repute is no guarantee of the possession of even the most modest outfit of medical knowledge. In the last ten years we have probably had as medical pupils nearly four hundred men now graduates, and therefore speak of what we do know, and do not feel disposed to consult boarding-house-keepers and bankers. Men of ability graduate and finally rise to eminence, but God only knows the amount of injury they do whilst they are learning their profession after they graduate. This is the real curse of our American system; not merely that we turn out a large number of ignoramuses, who flounder for a few years, trifling, it may be, with a few score of lives, and then fall out of sight, but that so many of our good practitioners become such at the expense of those wretches who fall in their way during the early years of their practice, and that many even of these good practitioners are ignorant of the outer knowledge of the profession,—totally unfit to guide their respective communities in regard to those matters, such as hygiene, which ought to be settled by physicians, and for direction in which the laity looks to the profession.

We have not space here for further words about deficiencies of which we had thought everybody knew. *Ex uno omnes disce*. Very many graduates of medicine from our first colleges have no practical knowledge of physical diagnosis.—Eds. P. M. T.]

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 21, 1874, TO APRIL 27, 1874, INCLUSIVE.

- BAILY, J. C., SURGEON.—Assigned to duty at Frankfort, Kentucky. S. O. 61, Department of the South, April 20, 1874.
- GARDNER, WILLIAM H., ASSISTANT-SURGEON.—Assigned to duty as Post Surgeon at Fort Union, N. M. S. O. 32, District of New Mexico, April 14, 1874.
- MIDDLETON, P., ASSISTANT-SURGEON.—When relieved by Surgeon Baily, to comply with S. O. 78, c. s., War Department. S. O. 61, c. s., Department of the South.
- LIPPINCOTT, H., ASSISTANT-SURGEON.—Assigned to duty as Post Surgeon at Fort Whipple, A. T. S. O. 35, Department of Arizona, April 9, 1874.
- DE WITT, C., ASSISTANT-SURGEON.—Assigned to duty at Humboldt, Tennessee. S. O. 61, c. s., Department of the South.
- GIRARD, ALFRED C., ASSISTANT-SURGEON.—Relieved from duty in Department of the South, and assigned to duty at the United States Military Academy, West Point, New York; so much of S. O. 79, c. s., A. G. O., as grants him four months' sick leave, having been revoked. S. O. 90, A. G. O., April 25, 1874.
- GIRARD, J. B., ASSISTANT-SURGEON.—Assigned to duty as Post Surgeon at Camp Lowell, A. T. S. O. 35, c. s., Department of Arizona.
- POPE, B. F., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon De Witt, to comply with S. O. 78, c. s., War Department. S. O. 61, c. s., Department of the South.
- FITZGERALD, J. A., ASSISTANT-SURGEON.—Relieved from duty at the United States Military Academy, and to report in person to the Commanding Officer, Department of the Columbia, for assignment. S. O. 90, c. s., A. G. O.
- MOFFATT, P., ASSISTANT-SURGEON.—Assigned to duty at Fort Garland, C. T. S. O. 32, c. s., District of New Mexico.

SATURDAY, MAY 9, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE.

OUR EYES—HOW TO TAKE CARE OF THEM.

Abstract of a Lecture delivered at the University of Pennsylvania,

BY WM. F. NORRIS, M.D.,

Clinical Professor of Ophthalmology.

Reported by S. D. RISLEY, M.D.

GENTLEMEN,—I purpose to-day occupying the remainder of the hour by directing your attention to an important branch of hygiene: the proper care of our eyes,—how we may best prevent disease of these important organs and prolong their period of usefulness. I need scarcely tell you that our eyes are the principal portals to the mind; that through their agency we acquire most of our ideas. Neither need I dwell upon their importance in the pursuit of our daily avocations, or the inestimable calamity caused by total loss of sight. An old German proverb tells us that “a blind man is a poor man;” and, although the self-evident truth of this statement comes home to us all, nevertheless the minor degrees of impairment of vision which diminish the capacity of the individual for continued work, or exclude him altogether from many profitable occupations, have not met with that attention, either from the mass of the profession or from the public, which they really deserve. In many cases these visual defects are acquired, being the result of improper use of the eyes; in others, they are caused by certain congenital anomalies in the organ itself.

My purpose to-day, gentlemen, is to give you, so far as the time will admit, some hygienic rules for the prevention of the first, and also the means for obviating the difficulties arising from the second.

In order to comprehend fully what I shall say, it may be necessary to recall to your minds certain facts in the physiology of vision. The eye may be considered, optically, as a dark chamber, with refracting media, the most important of which are the cornea and the crystalline lens, and with a receptive screen—the retina. As in the photographic camera, when the receptive screen is placed at the principal focus of its lens, parallel rays, or those from an infinite distance, are brought to a focus upon the screen, giving a distinct but inverted image of the object, so, in the emmetropic or optically normal eye, rays of light emanating from distant objects are, without effort, focused upon the rods and cones of the retina, giving, as in the case of the camera, a clear but inverted image of the object.

I say focused upon the *rods and cones* of the retina, for it is only here they can be perceived, it being the only perceptive layer of the retina; the other layers serve either to augment the intensity of the perception or to assist in conveying the impression to the central nervous system. If, in the camera, the receptive screen be placed either within

or outside the principal focus of its lens, we will have no longer a distinct image of the object, but a disk of diffused light; and, in order to obtain a clear picture again, we must increase or diminish its power of refraction. If the screen be placed nearer to the lens than its principal focus, we must increase its power of refraction by adding to it an additional *convex* lens; or, if outside the principal focus, diminish its refractive power by the addition of a suitable *concave* lens.

All objects nearer than infinity no longer send parallel, but divergent, rays; so that the screen remaining at the principal focus of the camera lens, the object being placed nearer than infinity, we would no longer have a distinct image pictured upon the screen, but a disk of diffused light again; and, in order to secure an accurate image, must either move the screen farther from the lens than its principal focus, or, as in the other case, increase its power of refraction by an additional lens, which will so bend even divergent rays as to unite them at the principal focus.

The eye, gentlemen, like the camera, is subject, also, to this law of conjugate foci; but the retina cannot change its position as the object approaches it. The eye, however, does possess the power of increasing the convexity of its lens, and thereby its refractive power, so as still to focus rays of light from near objects, or divergent rays, upon the rods and cones. This is known as the power of accommodation of the eye, and is dependent upon the ciliary muscle. The eyes being simultaneously directed to the observed object, the nervous influence passes along the third pair to the ciliary muscle, causing it to contract, thereby relaxing the suspensory ligament of the lens. The elastic lens is now allowed to expand, increasing its convexity, and thus its power for bending rays of light.

This power of accommodation has its limit, which differs at different periods of life. Thus, in youth it ranges in the emmetropic eye from infinity up to three inches from the eye. This near point retreats from the eye with increasing years; gradually, however, so that it is not noticed usually until about the fortieth year. Indeed, for ordinary employments, the recedence of the near point is not even then noticed. If a fine silk thread, stretched taught, be held at the nearest point of distinct vision, you will find that at the tenth year this will be at $2\frac{3}{4}$ ", at the twentieth year at $3\frac{3}{4}$ ", at the thirtieth at 5", at the fortieth at 8",—at which time the phenomena of old sight (presbyopia) begin to be manifested. At first only by artificial light, or when reading unusually fine print, it is noticed that vision is somewhat defective. Later it becomes impossible to obtain a distinct view of ordinarily fine print without holding it inconveniently distant from the eye, or by supplementing the accommodation by convex glasses. This diminution of the accommodation is not so much due to a diminution of the power of the ciliary muscle as to the hardening and loss of elasticity of the lens itself. You may readily convince yourselves of this by removing the lens from any child's cadaver, and comparing it with that of

an adult over forty. On examination, you will see that the child's lens is colorless and soft, while that of the adult has become hard and its nucleus is of a straw-yellow color. With advancing years, then, the lens becomes less elastic, and more firm in its structure; so that, though the suspensory ligament may be relaxed, it refuses to expand as in youth, and the individual is said to be old-sighted, or presbyopic, and must henceforth aid his sluggish lens by spectacles. For this purpose convex spherical lenses are usually placed before the eye, and of sufficient strength to bring the near point up to a comfortable distance from the eye. The numbers, gentlemen, affixed to these glasses, represent in inches the principal focal distance of the lens. Thus, a glass which will give a clearly-defined image of the sun one inch behind its centre is taken as the standard ($\frac{1}{1}$); a lens which gives the picture at two inches has only half this refractive power, and is denominated $\frac{1}{2}$; one which gives it at eight inches, $\frac{1}{8}$, etc. A point at this distance from the lens is called its principal focus; that is to say, the point at which the lens is able to focus parallel rays of light. Suppose, however, that our source of light, instead of being at an infinite distance, is near to us, we will find that the focal point has receded from the lens, and just where its new focal point will be may be determined by subtracting the distance of the object from the lens from the principal focus of the lens. Suppose, for instance, that we have a convex lens whose principal focus is ten inches ($\frac{1}{10}$), and we wish to obtain with it a distinct image of a candle placed twenty inches in front of it, where shall we place our screen in order to get a distinct image of it? $\frac{1}{10} - \frac{1}{20} = \frac{1}{20}$, and we will, therefore, obtain a focus for the rays emitted by the candle at 20" behind the lens.

There are also concave lenses, which cause the dispersion of parallel rays. The focus of such a lens is to be found by following the diverging rays back towards the source of light, and they are rated in the same way as convex lenses: *e.g.*, a concave glass of ten inches focus will render parallel rays as divergent as though they had come from a point ten inches in front of it. The strength of such a lens may readily be determined, also, by neutralizing it by a corresponding convex glass. If a weak convex or concave glass be moved rapidly before the eye, objects seen through it will appear to dance. If, however, such a concave glass is exactly neutralized by the apposition of a convex lens of equal power, objects seen through the combination, when moved rapidly in front of the eye, would seem stationary, as they do with a sheet of plate-glass under similar circumstances.

If I have made plain to you these laws,—viz., that the focus for parallel rays is always the same for the same glass, and that, in case of convex lenses, an approach of the object to the lens will cause a corresponding retreat of the image from its optical centre,—it will be obvious to you that, theoretically, an emmetropic eye could be focused for near objects either by lengthening its axis or by adding to it a suitable convex lens. From these considerations you will also gain an accurate idea of the change

which must take place in the crystalline lens in the act of accommodation.

That the crystalline lens does, in fact, become more convex in accommodating for near objects, may be proved by the change in the relations of the images reflected from its surface,—as in the so-called catoptric test,—and has been demonstrated by this means. You will see the same principle illustrated by looking into the brightly-silvered garden globes of different sizes. As your reflected image varies in size with that of the globe, so as the convexity of the crystalline lens increases or diminishes with accommodation the image will be smaller or larger, at the same time changing its relative position. As I have already told you, this power of accommodation is resident in the ciliary muscle and the lens itself. This will be rendered clearer, perhaps, by reference to the diagram which I show you (see figure), in which one-half of the lens is represented in the act of accommodation. You will observe that the ciliary muscle, acting from its fixed point at the corneo-scleral junction, is swollen and shortened in the act of contraction, by which act the suspensory ligament is relaxed; and you see the elastic lens has become thicker or more convex, and its radius of curvature much shorter, than that of the other half, which is represented as being in a state of rest.

DIAGRAM SHOWING THE CHANGE OF LENS AND CILIARY MUSCLE IN ACCOMMODATION.—*a*, Ciliary muscle in state of rest; *b*, in contraction.

Another point of considerable clinical importance is the fact that our perception for objects has its limits. Objects, therefore, must have a determined size to be seen at a given distance. Observation has determined the fact that printed letters presenting an angle of five minutes can readily be discerned by a normal eye. Suppose our eye placed at the centre of a wheel the radius of which is twenty feet, it will be able to recognize any object on the circumference of the wheel which subtends an angle of five minutes. Snellen has utilized this fact for clinical purposes in the construction of letters which, for the distances at which they are intended to be seen, subtend an angle of five minutes, and the individual strokes of each letter of one minute.

An emmetropic or optically normal eye will, if there be no opacity of its refracting media or disease of its inner coats, be able to recognize Snellen No. XX. readily at twenty feet, and will by an effort of accommodation be able to read No. I. at one foot, and the intermediate type at corresponding distances.

There are many persons, however, in every community, whose eyes have not this optically perfect construction (emmetropia), and all such optically imperfect eyes are designated as ametropic.

We saw that the emmetropic eye was so constructed that parallel rays of light were without effort

focused upon the perceptive layer of the retina. Now, we may have two fundamental departures from the normal type, called, respectively, *hypermetropia* and *myopia*. In the first, the antero-posterior axis of the eye is too short in comparison with its refractive power,—i.e., the retina is placed within the principal focus of the refractive media; consequently, the rays of light are intercepted before reaching the focal point, so that instead of a clearly-defined image upon the rods and cones there is a disk of diffused light, or a blurred and indistinct perception of the object. In the second condition, or myopia, refractive power of the eye is too great for its length of axis; consequently, the rays of light are focused in front of the retina, cross over, and, on reaching the rods and cones, give again a circle of diffusive, and consequently indistinct, vision. Such eyes are near-sighted, for they are able only to focus upon the retina rays of light which enter as *diverging* rays, while the first, or hypermetropic eye, in a state of rest, can focus only *converging* rays.

In myopia, in order to correct the optical defect and thus secure to the patient distant vision, we must place before his eye a glass which will make parallel rays of light thus divergent,—viz., a concave lens, the strength of the glass depending upon the degree of myopia: e.g., if a person is able to read No. I. of Snellen types at 12", which is the farthest point he can see it distinctly, and is unable to see No. II. at 24", and can see No. II. distinctly only when approached to 12", he has probably a myopia of $\frac{1}{12}$, which will be corrected for parallel rays or distant vision by a concave glass of twelve inches focus. With this glass, if his eye be otherwise healthy, he will be able to read Snellen XX. at twenty feet.

To the too short or hypermetropic eye, however, all objects must be indistinct, since in a state of rest it can focus on its retina only converging rays, and most objects in nature send to us either parallel or divergent rays; therefore, such an eye at rest must, in order to see objects distinctly, be aided by some optical contrivance which will cause even parallel rays to enter it as converging rays. We have seen, however, that the accommodation furnishes the emmetropic eye with the power of adding to itself an additional convex lens, and so focusing even diverging rays upon the retina. This power, indeed, is essential in all use of the emmetropic eye for near vision. In hypermetropia, however, it becomes necessary, even for distant vision, to use the accommodation if objects are to be seen distinctly. Such a person, you will observe, gentlemen, starts in life with a deficit which he is forced to make good by an effort of accommodation. Hence, in estimating the amount of nerve and muscular force required by him in accommodating for near objects, we must add this deficit to the amount employed by an emmetropic eye. This extra *load*, as it were, soon becomes an irksome one, and to its possessor proves one of the greatest evils of life. If able by his accommodation to overcome the anomaly and thus secure distinct vision, it is only to be tormented by ciliary neuralgia, injected and burning or itching eyelids, which may result in inflammatory conditions. With advancing years, as

his lens becomes more dense and less elastic, he finds himself unable to secure by the utmost effort distinct vision, and so resigns himself to his fate, being content to get his impressions of surrounding objects from a misty and indistinct image.

These difficulties, painful and serious as they are, may be entirely obviated by the use of convex spectacles,—glasses of such strength as shall correct the optical defect.

Thus, gentlemen, I have called your attention to three varieties of eyes: the *emmetropic* or optically normal eye, which in a state of rest is able to focus parallel rays of light upon the retina; the *hypermetropic* or "long-sighted" eye, which is too short in its antero-posterior axis, so that parallel rays are intercepted before their focal point; and the *myopic* or short-sighted eye, which is too long in its antero-posterior axis, allowing the rays to reach their focal point and cross over before reaching the retina.

In my next lecture I purpose to show you how many of us, starting in life with normal eyes, by neglect of proper hygienic measures, and by improper use of them, gradually acquire defects of sight which become serious hindrances to us in the pursuit of our ordinary occupations; and, further, how we may best guard against and prevent the development of such abnormal conditions.

ORIGINAL COMMUNICATIONS.

OBSERVATIONS ON THE NORMAL PULSE, RESPIRATION, AND TEMPERATURE OF PUERPERAL WOMEN.

BY G. WILDS LINN, M.D.,

Late Resident Physician to the Philadelphia Hospital.

THE importance of noting variations in temperature in physiological and pathological conditions or processes is now so well recognized, that any arguments adduced to prove it would be superfluous. The pulse and respiration have been noted from the earliest ages in the history of medicine, as giving information invaluable to the physician; and that a new factor has entered into the study of disease, affording such constant and certain evidence of its progress or decline, is reason for gratulation. The thermometer, as a means of physical diagnosis, is second to none of those which have lifted the science of medicine far above the plane it occupied but a score of years ago.

It was with such a belief in its revelations and predictions that I began and prosecuted a series of observations upon the temperature of lying-in women. These were made in the obstetrical wards of the Philadelphia Hospital, and extended over a period of three months, beginning in July and ending in October. The wards in which they were made had been unoccupied for months, had been thoroughly cleansed, and, being situated in a building entirely separated from the surgical wards, were removed from all danger of infection by them. They were also in the fourth story of the building, abundantly supplied with light, and well ventilated.

Hence it was that the circumstances under which these observations were made were of the most favorable character, and it is a noteworthy fact that there was not a single case of puerperal fever in the wards during the term, although there were the usual number of instrumental cases of delivery. In a hospital of such size, and in obstetrical wards where three hundred patients are confined annually, possibly no more auspicious time could have been selected for procuring such trustworthy results, my object being to ascertain the *normal* temperature, pulse, and respiration of the lying-in women.

To secure this result I have rejected all cases in which delivery was effected by means of instruments, those in which there was post-partum hemorrhage, and patients suffering from any intercurrent disease, as diarrhœa, malaria, phthisis, etc. I have rejected, also, all those who did not suckle their children. Our patients generally are strong, healthy women, averaging about twenty-four years of age, the greater part of them being domestics. I have selected only such cases, and from these excluded also, besides the above classes, all who had fissured nipples, or any other local lesion which I thought might mar the accuracy of my observations.

Adopting such a rigid course of pruning, I found my cases, over fifty in number, on which I had taken observations, diminishing until I had but twenty-four which I could call *positively normal*, or those into which no pathological element whatever might be found to enter. I should also say that in every case I made the observations myself. Those who have had any experience in hospital practice can realize how unsafe it is to trust to ward nurses for accurate information on questions of such nature in single instances; much more so, then, when a long period of time is necessary to complete an investigation.

Fahrenheit's thermometers were used, and the temperature in all cases taken in the axilla, ten minutes being allowed for each observation. To insure accuracy, which is a *sine qua non* in observations of this character, my thermometers were all compared with a standard thermometer, the value of each being carefully noted.

The pulse, respiration, and temperature were each taken twice daily, at 9 A.M. and 8 P.M., two and a half hours after the morning and evening meals. In this manner the increase in temperature due to digestion was avoided; also the minimum daily temperature, which, according to Lichtenfels and Frölich, occurs between 6 and 8 o'clock A.M. and between 10 P.M. and 1 A.M.; also the maximum daily temperature, which, according to the same authorities, is found between 4 and 5 o'clock P.M. My observations in every case were begun on the morning or evening immediately following delivery, and continued for nine days, it being customary in the hospital for patients to be kept in bed for that period after labor. Every possible attention was observed which it was thought might conduce to the welfare of the patients. No exertion whatever, on their part, was permitted after delivery. Each patient was allowed to remain an hour after parturition upon the "lying-in bed," which, resting on castors, was then wheeled into the ward and alongside the bed intended for her, and

she was then carefully lifted into it. Napkins were changed frequently each day, and a solution containing the permanganate of potassium freely used. No alcoholic stimulants were allowed. The diet consisted of milk, eggs, beef-tea, and mutton, with coffee or tea, and bread, toasted, or plain with butter.

I have arranged all my results in tabular form, so as to show at a glance (together with the age and pregnancy)—

1. The pulse, respiration, and temperature of each patient for the morning and evening of each day;
- 2, the average morning pulse, respiration, and temperature of each patient;
- 3, the average evening pulse, respiration, and temperature of each patient;
- 4, the average daily pulse, respiration, and temperature of each patient;
- 5, the average morning pulse, respiration, and temperature of the whole number for each day;
- 6, the average evening pulse, respiration, and temperature of the whole number for each day;
- 7, the average daily pulse, respiration, and temperature of the whole number for each day;
- 8, the average morning pulse, respiration, and temperature of the whole number for the whole time;
- 9, the average evening pulse, respiration, and temperature of the whole number for the whole time;
- 10, the average daily pulse, respiration, and temperature of the whole number for the whole time.

I had hoped to present with these tables a general review of all the published observations of a similar nature which have been made abroad. These are, however, few in number, and the major part of them are untranslated, and found only on the shelves of the Continental libraries. As I expect to have access to these soon, I shall then be able to review the whole subject satisfactorily. I have presented my tables complete, for I am sure that after they have been examined my deductions can be much more readily comprehended. I was anxious, too, that every step I had taken in reaching my conclusions should be perfectly understood, for it will strike the mind of the reader that some of them do not support the general if not universal opinion of the profession in regard to the so-called "milk fever" attending the establishment of the milk secretion, which occurs generally from thirty-six to seventy-two hours after delivery, and is supposed to give rise to an increase in temperature of one, two, or even more degrees.

The belief that such a rise in temperature does occur has been accepted by medical men for centuries: so thoroughly, indeed, has the mind of the profession been imbued with this idea that it would be deemed rash in any one to question it, unless he were supported by an array of facts which could not be ignored.

Attending this milk fever, and even more marked than the rise in temperature, has been a supposed increase in the frequency of the pulse, so that a pulse of 90 or 100 per minute is generally considered as indicative of nothing more than a process altogether physiological.

I have selected twelve cases complicated by fissured nipples. These I have tabulated also as the others, and the results from them I have placed alongside those obtained from normal cases. An

3. That the number of respirations is increased if the statement of physiologists be received, that the

The following tables contain the records of the original observations upon which the above conclusions are founded. On account of the importance of the subject, they are here appended in full, in order that the grounds of the conclusions reached may be examined by any one sufficiently interested to perform the labor of so doing.

TABLE I.

“ daily “ “ “ “ “	80	26	100.2

	Pulse.	Resp.	Temp.
Average Pulse, Respiration, and Temperature of the entire number of Cases for the time observed, deduced from Table III....	80	26	100.2

TRANSLATIONS.

PULSATION OF THE SUBCLAVIAN AS A SIGN OF SUPERIOR DILATATION OF THE AORTA.—Contrary to what is observed under normal conditions, there may be noticed in certain cardiac affections peculiar pulsations in the carotid region, and at the base of the neck. That these pulsations originate in the passage of the blood-current through a large artery—the subclavian—may be shown in two ways: first, by placing the finger back of and below the tubercle of the scalenus anticus muscle, when this artery will not be found in its usual position; then by making compression over the seat of pulsation, when the pulse at the wrist is affected. If on making this compression over the misplaced subclavian the arterial walls are lightly impressed by the finger, a double vibratory tremor may be remarked. The first and most intense part of this is systolic, and is evidently produced by the rapid centrifugal passage of the blood-current. The second, of variable intensity, is caused by the return of the blood towards the heart; it is sometimes wanting.

Auscultation over the seat of pulsation demonstrates the existence of a double blowing murmur, evidently connected with the vibratory tremor above mentioned. The second part of this murmur is wanting when the second part of the tremor is absent.

In a number of autopsies of such cases, the existence of aneurism affecting the superior wall of the aorta was ascertained. In these cases the subclavian is found displaced, and overlapping to a certain degree the omohyoid muscle. It is at first uncovered behind the clavicle, and then becomes more superficial. Finally, it is sinuous,—that is, too long for its channel.

The double tremor and murmur appear to be independent of any abnormal condition of the aortic orifice. The fact appears to be that the walls of the dilatation, true or aneurismal, having lost their elasticity, allow themselves to become distended under the influence of the ventricular wave at the same time as the arterial system. But, owing to the impulsive force of the heart having been exhausted by the inertia of these walls, the arterial tension is lessened.

The diastolic reflux of a part of the contained blood results of necessity from this unequal subdivision of the blood-tension. It is the centripetal reflux which determines the diastolic murmur. The displacement of the subclavian is evidently due to elevation of the superior wall of the aorta. It is shown in the shortening of the course of the carotid and other vessels given off, causing them to become sinuous, and thus to give rise to the pulsations noted. If the aortic dilatation is equal over all parts whence the great vessels are given off, the various phenomena alluded to will be observed equally on both sides of the neck. If, on the contrary, it is greater near the aortic origin, or on the other extreme of the arch, pulsation, etc., will only be observed on the affected side.

We have here, then, a valuable aid in the diagnosis and prognosis of superior aortic aneurism. For not only may the extent and position of the enlargement be ascertained approximately, but if in the progress of the case the vibration and murmur should disappear we may hope that the aneurismal pouch is being filled with clots.—*Archives Gén.* (by A. Fauvre). A. V. H.

SECTION OF THE BUCCAL NERVE THROUGH THE MOUTH.—In a note read before the Académie de Médecine (*Archives Gén.*, Feb. 1874), Dr. Panas, after a résumé of previous operations, gives the following as performed by himself:

The patient, unanæsthetized, being seated in a good

light, the head is firmly fixed by an assistant, who also keeps the jaws separated by placing his fingers, properly protected, between them on the sound side. On the other side the commissure of the lips is held back by an instrument so that a good view is obtained of the inner side of the cheek, and the operator, using his finger as a guide, makes an incision parallel to the edge of the maxilla, beginning on a level with the middle of the superior molar, and extending to a point opposite the crown of the last inferior molar. This incision, which is from two-thirds of an inch to an inch in length, only extends through the mucous membrane, and exposes the deep fibres of the buccinator without loss of blood. The operation is then continued by short and careful strokes of the knife, or by curved scissors; the only vessels liable to be cut being the buccal nerve and the artery, which lies in juxtaposition to the nerve, and which may be readily closed by torsion. The buccinator being divided, the nerve may be searched for by means of a strabismus hook. It may in general be readily found at the bottom of the wound and in connection with the buccal artery; when hooked on the instrument it causes an acute and characteristic paroxysm of pain, and, being identified, may be excised as desired.

The advantages of the operation, according to Dr. P., may be briefly stated to be comprised in the absence of danger from wounding the facial artery or nerve or the duct of Steno. Even should this duct be wounded, the inconvenience of salivary fistula is avoided, since the opening would be within the mouth.

In the case operated upon in this manner by Dr. P., but little pain followed the operation. Cicatrization of the wound occurred on the sixth day, and the neuralgia, which had formerly been very severe, disappeared entirely. A. V. H.

INFLUENCE OF PREGNANCY UPON DISEASES OF THE HEART.—In a clinical lecture reported in *L'Union Médicale*, January 27, 1874, M. Sée offers the following conclusions on this subject. As regards the prognosis of heart-diseases in connection with pregnancy, much depends on the lesion which may exist in any given case.

From this point of view M. Sée divides heart-diseases into several categories. *Aortic narrowing* is an affection of old age, and out of question in these cases. *Aortic insufficiency* is not uncommon among young girls and women. This is not, however, dangerous in pregnancy when uncomplicated by functional troubles, and M. Sée cites six cases coming under his notice, in which a number of pregnancies had terminated under these circumstances with entire safety to mother and child. He concludes it unnecessary to interdict marriage under similar circumstances.

Mitral affections are much more grave, but these differ considerably as to the prognosis they give rise to. In *mitral narrowing*, provided there is no pulmonary congestion, no cedema of the inferior members, no cerebral emboli,—if, in a word, the disease is characterized only by a presystolic bellows-murmur, although this may be most intense, and even accompanied by whining (pialement),—in this case the narrowing cannot exercise any evil influence on the course of pregnancy. M. Sée gives here several interesting cases in illustration, and concludes as follows:

"Although there is nothing to interdict marriage in cases of mitral narrowing, yet it is quite different in *mitral insufficiency*; above all when there are congestive accidents on the part of the lungs.

"In such cases it is necessary to advise against marriage, since pregnancy would always be dangerous."

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 9, 1874.

EDITORIAL.

THE CENTENNIAL.

THE papers teem with editorials, telegrams, extracts, concerning that absorbing topic the Centennial. Congress and the Centennial, Councils and the Centennial, the ladies, the workingmen, the business men and the Centennial, are the order of the day; and to these we would add a thought concerning that interesting being, the busy practitioner, and the Centennial. What are his relations to it, and its to him? Will he be better for it, or worse? Will he have much to do with it, indeed? For the busy practitioner is a being on whom the agitations of the day make little impression. Thrones crumble, republics are convulsed, epidemics rage, conflagrations devastate, yet the busy practitioner pursues the even tenor of his way. Gala-days and days of rest find him alike jogging on his rounds. The revolutions which stir his soul are those of medical science. If politics engage him, he ceases to be the busy practitioner, and becomes a non-descript; yet he takes a thoughtful interest in everything that concerns his world. The theme that interests his clients awakes an answering interest in him. As he reads, if he gets the chance, his daily paper, he must be asking himself to-day what is the Centennial to him. We answer for him, much and little. He helps to pay for it; perchance it diverts also the capital which would find its truest uses in settling his long-standing claims. Yet it bids fair to stimulate business, and other claims may be met more promptly. The Centennial will crowd the city

in the sickly season of the year, and busier will be those busy practitioners who know the entrances to our large hotels, whilst the less fortunate may glean a few fees from the comparatively barren fields of the boarding-houses. The long sunny stretch to George's Hill will yield its quota of over-heated foreigners; the long round of sight-seeing, of over-taxed and over-wearied bodies and minds; and if the whilom exotic, the American drink, blossom more fully in native soil, then may we look for multitudinous mania-a-potu and teeming delirium tremens. But we wot that the average busy practitioner will long for none of these things, the public opinion notwithstanding. His soul rather thirsts for the quiet summer, when the great houses are deserted, and children's excursions keep the poor off the sick-list, when he can by snatching a week from the fifty-two be happy in the country or at the sea-side, and forget the remorseless year, till it seizes him again and chains him in the treadmill of his daily rounds.

But we must make our show in the Centennial. We cannot exhibit to the world our truest work, our successes or our failures; but the inventions we claim as ours, the mechanical appliances, the instruments to facilitate research,—these, our instrument-makers, inspired by us, will set before the visitors. Perchance the College of Physicians might be moved to place beneath the great Memorial dome that marvel of art, the plaster model of the Siamese Twins from the waist upwards, that memento of an unrivalled duplicity which has cost the College so dear. What portion of the globe of Europe, Asia, or Africa could produce the equal of that unique, mysterious figure?

The inventive American mind, before which impossibilities are but incentives to performance, spurred by the coming Centennial, could devise, if it willed, in the two years before it, new apparatus, new remedies, new operations enough to astonish Europe. It could fill the great Memorial building with new medical literature—Heaven help the readers!—and call up new diseases from the vasty deep, and diagnose and treat them for the edification of a shuddering world. But enough; let us all be up and doing, and perchance on some sultry July day of 1876 we may see the jaded, fly-bitten horse of the busy practitioner slowly jogging towards George's Hill to catch a chance hour or two for its owner to wander amid the curiosities that America has gathered together to play with for a little, till the toys are old and broken and the child of a hundred summers is tired of play.

THE IDENTIFICATION OF THE REMAINS OF DR. LIVINGSTONE.

THE hold that the superstition of burial has upon the English race, and the probabilities cremation has of becoming popular, seem to us to be plainly outlined in the excitement in regard to the recovery of the body of the great African traveller and philanthropist. To us the one important point has been the recovery of his diaries and other papers and records. Yet we hear very little about this, although the newspaper press has teemed with particulars concerning the body. When the latter reached England, the question of its identification was of course an important one. As the readers of "Livingstone's Travels" will remember, some years ago he was seized by an infuriated dying lion, and his left arm very much lacerated, the bone being crushed to splinters: from these wounds he recovered with an ununited fracture. Dr. Livingstone had during life consulted very freely Sir William Fergusson concerning this arm, and to him were intrusted the examination and identification of the body. In his report he says, *inter alia*:

"From what I have seen I am much impressed with the ingenious manner in which those who have contrived to secure that the body should be carried through the long distance from where Livingstone died until it could reach a place where transit was comparatively easy, accomplished their task. The lower limbs were so severed from the trunk that the length of the bulk of package was reduced to a little over four feet. The soft tissues seem to have been removed to a great extent from the bones, and these latter were so disposed that by doubling and otherwise the shortening was accomplished. The abdominal viscera were absent, and so were those of the chest, including, of course, heart and lungs. There had been made a large opening in front of the abdomen, and through that the native operators had ingeniously contrived to remove the contents of the chest as well as of the abdomen. The skin over chest, sternum, and ribs had been untouched.

"Before these points could be clearly ascertained, some coarse tapes had to be loosened, which set free some rough linen material—a striped colored bit of cotton cloth, such as might have been an attractive material for the natives among whom Livingstone travelled,—a coarse cotton shirt, which doubtless belonged to the traveller's scanty wardrobe, and in particular a large portion of the bark of a tree, which had formed the principal part of the package,—the case thereof, no doubt. The skin of the trunk, from the pelvis to the crown of the head, had been untouched. Everywhere was that shrivelling which might have been expected after salting, baking in the sun, and eleven months of time. The features of the face could not be recognized. The hair on the scalp was plentiful, and much longer than he wore it when last in England. A moustache could not

be recognized, but whiskers were in abundance. The forehead was in shape such as we are familiar with from memory, and from the pictures and busts now extant. The circumference of the cranium, from the occiput to the brow, was twenty-three and seven-eighths inches, which was recognized by some present to be in accordance with such measurements when alive.

"In particular the arms attracted attention. They lay as if placed in ordinary fashion, each down by the side. The skin and tissues under were on each side shrunk almost to a skeleton bulk, and at a glance to practised eyes—there were five, I may say six, professional men present—the state of the left arm was such as to convince every one present who had examined it during life, that the limb was Livingstone's. Exactly in the region of the attachment of the deltoid to the humerus there were the indications of an oblique fracture. On moving the arm there were the indications of the ununited fracture. A closer investigation and dissection displayed the false joint, which had long ago been so well recognized by those who had examined the arm in former days. Thousands of heads with a like large circumference might have been under similar scrutiny; the skeletons of hundreds of thousands might have been so; the humerus in each might have been perfect; if one or both had been broken during life it would have united again in such a manner that a tyro could easily have detected the peculiarity. The condition of ununited fracture in this locality is exceedingly rare. I say this from my professional experience; and that such a specimen should have turned up in London from the centre of Africa, excepting in the body of Dr. Livingstone, where it was known by competent authorities to have existed, is beyond human credibility. It must not be supposed by those who are not professionally acquainted with this kind of lesion—which often causes so much interest to the practical surgeon—that a fracture and new joint of the kind now referred to could have been of recent date or made for a purpose."

CORRESPONDENCE.

SLOWTOWN, April 25, 1874.

MY DEAR SIR,—Perhaps you do not know our town,—I beg its pardon, our city; it is not so big a place as it seems, but it delights in two medical colleges. Once, a good while ago, we were foremost in trade and even in literature; but nowadays we have lived to see the trade run away, and to find ourselves reduced to one poet, and he absent in Europe. But then we have still two schools of medicine, which you know make us a medical centre,—the medical centre, we like to call ourselves. The mode of management of these schools is interesting; and, as I hear you are rather discontented about yours, you might like to know how we do it. The managers are chosen chiefly, I may say solely, with reference to their knowledge of medicine; one of the school boards having no medical men, but being made up of retired politicians, bankers,

judges, and lawyers, in and out of work. All of them, however, have, in their time, paid doctors' bills; the judges have heard, and the lawyers examined, medical experts, who have been called upon to testify in murder cases, also; the bankers have furnished letters of credit to doctors who were going to Europe: so that you see they are thus, in one way or another, educated into entire fitness to make a correct choice. I ought to add that the charter provides that in the year 1900 one-half of the trustees shall be elected by the alumni. This is a far-seeing and wise provision, because it is well known that as yet physicians are incapable of knowing who can lecture or who cannot, who has written original papers and who has not; whereas it is earnestly hoped that by the year 1900 they will have come to know as much about it as do lawyers, judges, or ex-politicians. There is, in regard to elections, a very good rule, or set of rules. "The persons who elect are called trustees, which is supposed to be remotely derived from the word trusty; in other terms, trustee is a corruption of the word trusty, and is one of those absurd derivatives of which the dictionaries make so much. They are bound by an oath to choose the best man, which, of course, prevents them from pledging themselves, since it might chance that the best man, or a better, might turn up at the last minute. They collect the opinions of prominent medical men, go and hear the candidates lecture, and thus discriminately reach a choice. Unfettered, however, by such narrow means of judging, they are also open to other and larger influences.

Perhaps it may be well to illustrate this by the ways of the lower creatures known as candidates. These engage in what is called a canvass, which the dictionaries define as a coarse material intended to catch the wind. Each candidate sends all of his friends to call on every trustee. If ten thousand persons call on a trustee, he is obliged by law to vote as they wish. If you are a candidate, and are wise, you ask your grandmother to ask somebody else's grandmother to ask her aunt to get her clergyman to see Mr. So-and-so and to get him to ask his grandmother to request her grandmother to ask Mr. B. to vote for Dr. Q. This is called influence, and whichever fellow has most grandmothers gets the place.

If you do not use this method in Philadelphia, I respectfully suggest its immediate adoption.

Yours,

LANCET.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, MARCH 26, 1874.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

DR. J. EWING MEARS presented specimens of *mammary cancer* removed from a patient aged 46 years. The portions exhibited were removed at the

third operation which Dr. Mears had performed upon the patient. At the time of the first operation the entire gland was excised. In a year from this date the disease reappeared in the cicatrix, and two small masses were removed, one of which had undergone ulceration. Eight months following the second operation three nodules of cancerous tissue were excised, the development and growth of these having been very rapid. After the third operation the patient was attacked with pleuro-pneumonia, which terminated fatally in a few days.

In presenting these specimens to the Society, Dr. Mears desired to direct the attention of the members to a method of treatment which had been pursued in this case, and to exhibit the results as shown in the specimens. A short time prior to the first operation, and after the full development of the tumor, the patient was examined by Dr. Washington L. Atlee, in consultation, at whose suggestion the administration of *arsenic* was commenced. The form employed was the official liquor potassii arsenitis, which was given in *two-drop* doses. The medicine was administered without interruption from the time of the first operation until the second,—a period of one year. During this time the patient's general health was remarkably good. There appeared to be an entire absence of that condition designated the "cancerous cachexia." Her appetite was not at all interfered with, and there was no loss of flesh or strength. The return of the cancerous growths in the cicatrix was unattended by pain, from which she had suffered severely during the development of the primary tumor. The portions removed at the second operation were submitted to a careful microscopical examination by Dr. Tyson, and pronounced by him to be specimens of scirrhus. He noted an extreme degree of fatty degeneration in the cells of the structure,—nothing to indicate any impression made upon this secondary growth by the long-continued use of the arsenic.

A good recovery followed the operation, and the patient was again placed upon the arsenic; in five months *three* small masses were observed, one occupying the site of the cicatrix, one about two inches above, and one about one inch below it.

The patient's health was not so good after as before the operation; her strength began to fail, and in other ways she manifested a decline of her former good health. The stomach was not affected by the use of the drug, so far as could be observed. It seems proper to ask that the specimens removed at the third operation should be referred to the Committee on Morbid Growths, for their examination. If these are found to be specimens of scirrhus, the conclusion is inevitable that in this case the remedy was ineffectual in modifying the character of the growth.

The test was made under the most favorable circumstances; the social condition of the patient was such that all directions were strictly enforced; the arsenic was taken regularly and without intermission. The specimens as removed have been submitted to careful microscopic examination, and their character definitely determined.

DR. JOHN ASHHURST, Jr., said that he believed that, with the exception of Prof. Parker, of New York, Dr. W. L. Atlee was the only surgeon of prominence who had any faith in the value of arsenic as a remedy for cancer. Even Prof. Parker did not go so far as Dr. Atlee, who claimed that, by the timely administration of the drug in question, what he called the "cancer-cell" could be "extinguished." Dr. Ashhurst had himself seen nothing, whether in his own experience or in the published reports of others, to lead him to suppose that arsenic had any effect whatever either in preventing the development of cancer or in arresting its growth.

With regard to the absence of cachexia, as reported in the case narrated by Dr. Mears, Dr. Ashhurst said that he thought it was now generally acknowledged by practical surgeons that the term "cancerous cachexia" was a misnomer, the fact being that those patients only became cachectic in whom the disease involved important internal organs, and that the cachexia in such cases was in no degree different from that observed in other cases of a non-cancerous nature. Thus, patients died from external cancer without any development of cachexia, while those in whom the so-called "cancerous cachexia" was best marked might be found after death not to have been affected with cancer at all.

Dr. MEARS said he did not wish to be understood as claiming the influence of arsenic in preventing cachexia; on the other hand, he did not believe in the existence of cachexia in *external cancer*, nor was he satisfied from what he had thus far observed that arsenic exerted any positive influence upon cancer; he had simply brought forward this case as bearing on the subject, which was the more important, since each specimen has been submitted to careful microscopic study, by means of which the true nature of the growths had been accurately determined. He further desired to elicit the opinions of members of the Society who may have had experience in the use of arsenic in cancer. He thought the only way to arrive at a correct conclusion in reference to the therapeutic value of the agent was to adopt the plan he had pursued in this case.

The specimen was referred to the Committee on Morbid Growths, which reported on April 9 as follows:

"The mammary tumors presented by Dr. Mears have a firm, glistening white appearance upon fresh section; very little soft fluid matter can be pressed out from them. Microscopically, the tissue is composed in greater part of thick and tough fibrous bands of the interstitial connective tissue; in this structure are imbedded nests of small, epithelial-like cells, which are seen in the various stages of fatty infiltration and degeneration. At a few points of the growths a distinctly tubular arrangement of the cells could be made out, as if the cancerous infiltration had originated in the tubules of the lacteal glands. No definite conclusion could be arrived at, however, as to the starting-point of the growths, since at many places nothing but a débris of fat-granules denoted the former site of the cancerous cells. The extremely wide and dense bands of the stroma crossing each other in every possible direction, and the almost complete fatty metamorphosis and absorption of the cellular structure, lead your committee to designate these nodules as retracting cicatrizing fibrous carcinoma,—the scirrhus proper."

The PRESIDENT presented a *portion of the thoracic wall from a case in which paracentesis had been successfully performed eighteen months before death*. There had been but little return of effusion, though the signs of plastic exudation and thickening of the pleura continued. Death resulted from chronic ulceration of the colon, in connection with granular kidneys. The point of puncture was in the sixth right intercostal space, about on the line of the anterior border of the axilla. The wound in the skin was visible as a minute white scar. There was no adhesion between the skin and intercostal tissues. The point of puncture on the pleural surface appeared as a minute round hole, one-eighth of an inch in diameter, with dark, discolored walls. The two layers of pleura were very dense, thick, and tightly adherent over the antero-lateral part of the chest. There was no adhesion directly beneath the point of puncture. The changes in the pleura did not seem specially marked in this neighborhood. The case is reported at length in a paper on the "Operative Treatment of Pleural Effusions," read before the Philadelphia County Medical Society on March 25, 1874, and published in the *Phil. Med. Times*.

Dr. JOHN ASHHURST, Jr., asked Dr. Pepper what his experience had taught him was the best position for the operation.

Dr. PEPPER replied that, in his experience, the sixth or seventh interspace in the line of the anterior part of the axilla was the best adapted for the majority of cases of large pleural effusion. In very numerous instances in which he had operated at this point he had never known a single disagreeable symptom to follow.

This was the site originally recommended by Trousseau. It is always dependent, and therefore allows much fluid to escape by gravity; it is easily accessible, the walls are thin, easy of perforation, and it is easy to retain a canula in this position, permanently, if it becomes necessary.

Dr. ASHHURST said that he was glad to find that Dr. Pepper's experience upon this point in a great measure coincided with his own. He had, in tapping the chest, always employed either Bowditch's suction-apparatus or the aspirator, and had usually chosen as the place of puncture a point between the fifth and sixth, or between the sixth and seventh, ribs. Upon one occasion, on which he had adopted a lower point, he had found that towards the close of the operation a good deal of pain was caused by the diaphragm rising against the extremity of the instrument. He had not tapped as high as the fourth intercostal space, as recommended by some British writers, but considered a lower position preferable. The best line for the puncture he thought to be that of the insertion of the serratus magnus,—somewhat posterior, therefore, to that adopted by Dr. Pepper,—as here the muscular covering of the chest-wall was thinnest.

Dr. PEPPER said that the site above the fourth rib sometimes recommended was, under the guidance of Laennec, followed by Walshe and others, with the idea of imitating nature, this being the seat where spontaneous evacuation generally takes place. It appeared to him that it had been based upon false reasoning; he thought the spontaneous opening takes place here, not because it is more advantageous, but because the walls are thinner, the intercostal spaces wider, and consequently the uniform hydrostatic pressure upon the inner surface caused yielding at this point first. This site is inconvenient, because the fluid cannot readily be entirely drawn off; and it may happen that adhesions might form as low down as this point after the operation, while the remaining fluid would gravitate into the more dependent portion of the thorax, and thus require a second tapping lower down.

Dr. J. H. HUTCHINSON presented the specimens from a case of *aneurism of the arch of the aorta*. The patient from whom they were removed was an Irishman, æt. 53, and a coachman by occupation, who was admitted into the Pennsylvania Hospital February 27, 1874. His history was obtained with difficulty, but it appears that three years ago he was overcome in consequence of the inhalation of irritating gases in a chemical laboratory in which he was at that time employed. After the illness which followed this, he suffered from habitual dyspnoea. Two days before his admission he had a chill, accompanied by pains in different parts of his body, and followed by swelling of the face, neck, and upper part of the chest. Although he denied it, it was discovered that he was addicted to drink; but he had never had rheumatism. When admitted, in addition to the swelling already alluded to, he presented a marked cyanotic discoloration of the face and neck. He had some dyspnoea, and an excessively feeble radial pulse. A physical examination showed dullness on the right side of the chest, continuous with the cardiac dullness, extending two inches from the sternum, and from the second to the fifth rib. In the same position a double murmur was heard; the diastolic murmur being harsher

and of higher pitch than the systolic; these murmurs were so loud that they were heard all over the chest. A decided impulse could be felt, but at no time could a thrill be discovered. There was no dysphagia, no dropsy, and no albumen in the urine. The pulse at the wrist was weak, but perfectly regular, and no difference could be detected between the beats of any of the corresponding arteries of the body. The symptoms increased in severity from day to day, the congestion becoming more decided, and giving rise to a very œdematous condition of the upper part of the body, especially on the right side; the cutaneous veins of the chest were enormously dilated. Around the lower part of the thorax these dilatations presented an arborescent appearance, and completely surrounded the body, like a girdle. On the 10th of March, the day of the patient's death, the whole of the right side of the chest anteriorly was dull on percussion, the dulness being sharply limited laterally by a line continuous with the posterior fold of the axilla. In the dull region the breath-sounds were feeble and distant, and there was an absence of vocal fremitus. Death occurred at 11 P.M., rather suddenly.

The *autopsy* was made twelve hours after death. The rigor mortis was well marked. There was no emaciation; the veins of the upper part of the body were enlarged. The right pleural cavity in front was filled with serum and clotted blood, which had been prevented from sinking to the lowest part of the cavity by the presence of adhesions. In the median line, above the pericardial sac and partly to its right side, was a large aneurismal sac, taking its origin apparently from the commencement of the transverse portion of the arch of the aorta, about three inches above the sigmoid valves, where the walls of the artery on the right side came to an abrupt termination, presenting an appearance very much as if they had been cut with a sharp knife. The aneurism, which appeared to have begun as a dissecting aneurism, and to have become diffused not long before the fatal termination,—probably at the time when the chill occurred,—extended from the arch of the aorta to the pericardium, resting upon the diaphragm, and partially compressing the right lung. The rupture was found in the wall of the sac on the right, near its upper part. The vena cava descendens was compressed by the aneurism.

Dr. Hutchinson said that the external coat of the aorta appeared to line the whole of the aneurism except at its lower part, where it was seen to terminate by a ragged edge. He called attention to the fact that the patient, although troubled with some shortness of breath, had been able to do his work up to two weeks before his death, when the chill occurred, which was followed by the symptoms caused by pressure on the cava descendens.

Dr. Hutchinson considered the case remarkable because the other pressure-symptoms were absent. Thus, although dyspnoea had existed some time before the patient came under observation, there was no evidence that either bronchial tube was compressed. There was no dysphagia, and the pupils were of equal size, and reacted to light. He thought the most curious feature of the case was the venous girdle, which recalled in its disposition herpes zoster, but differed from this in completely surrounding the body. It made its appearance in a single night; at least, it was absent at one visit and present at the next.

The PRESIDENT asked the members whether they had ever met with this extreme cyanosis and œdema of neck and chest-walls. While they are very frequent attendants of mediastinal tumors, he had rarely found the symptoms in thoracic aneurism. He also desired to know of Dr. Hutchinson how he accounted for the symptoms of cyanosis, whether by pressure or by the presence of a coagulum obstructing some of the large veins.

Dr. HUTCHINSON replied that the cyanosis was undoubtedly owing at first to pressure upon the cava descendens, and possibly upon the right vena innominata. Later, coagulation may have taken place in the right jugular and subclavian veins, as clots were found in these vessels after death. Towards the close of the patient's life the cyanosis was not so marked as before, in consequence of the establishment of the collateral circulation. Dr. H. was also impressed by the fact that the diastolic murmur was rougher and of higher pitch than the systolic. He had diagnosed the probable existence of aneurism, although the symptoms and physical signs, while they indicated unmistakably the presence of an intra-thoracic tumor, left the nature of this somewhat in doubt.

Dr. J. EWING MEARS said he had not examined the specimen very closely, but he thought the phenomena of pressure might be accounted for by the direction the tumor had taken, which was towards the right.

Dr. HUTCHINSON also presented an *aorta showing calcareous and atheromatous degeneration*, removed from the body of an old man, 75 years of age, who had died at the Pennsylvania Hospital with symptoms indicating obstruction to the circulation. During life no murmur was heard in any part of the chest, although a physical examination was repeatedly made; the symptoms appearing to indicate valvular disease. The man had also suffered in early life from rheumatism. A calcareous plate, an inch in length, was found in the upper wall of the arch of the aorta and in other parts of the vessel; its inner coat was the seat of extensive atheromatous changes.

Dr. H. remarked that occasionally murmurs were absent when all the physical conditions necessary for their production appeared to be present. In this case the examination of the heart was rendered difficult in consequence of the œdema of the walls of the chest, and of the existence of mucus in the bronchi, giving rise to mucous râles.

Dr. OSCAR H. ALLIS presented the larynx from a case of *pseudo-membranous laryngitis* in a child 14 months old, removed twenty-four hours after death. The child was taken suddenly ill on Sunday, March 22, about midday. It had been ailing for a few days with a slight cough, but its symptoms were hardly sufficient to attract attention. The first cause of alarm was extreme dyspnoea, simulating croup. He saw the case late in the afternoon. The child was then extremely restless, presenting every symptom of obstructed breathing,—forty respirations per minute, and with each the chest above the clavicle and below the sternum was deeply depressed. With the inspiration was a harsh and somewhat shrill or hissing sound.

The anterior nares were filled with a hardened mucus, and gave evidence of the presence of a slight catarrhal affection. The tongue was dry (the child was breathing with open mouth), and covered with dark-brown fur. The fauces and pharynx were inflamed, but there was no evidence of inflammatory deposit. There was no unusual heat of skin; no special evidence of fever, save excessive thirst. There was no pulmonary complication. The child lingered thirty hours, with no amelioration of these symptoms.

Autopsy, twenty-four hours after death.—Larynx swollen, with covering of distinct pseudo-membrane. Dyspnoea due probably to the swelling and amount of œdema, rather than to the abundance of pseudo-membrane. Membrane distinct in trachea below the cricoid cartilage, and could be easily floated off by a stream of water. Lungs healthy.

There were two circumstances prejudicial to surgical interference:

1. *The age of the child*.—This, as has been stated, was 14 months. Though few children survive the oper-

ation under four years, yet there are fourteen successful cases recorded under 24 months, and five cases under 14 months. The youngest case he had found recorded* was by Barthez, at 7 months.

2. *The surroundings.*—The child was an inmate of a "home for children," and it is needless to speak at length either of their condition at these "homes," even under the most favorable circumstances, or the privation and wretchedness from which they have been transplanted.

Dr. Allis desired an expression of opinion from the members of the Society as to the propriety of an operation in similar cases.

In an autopsy in a case of two and a half years, the membrane was found to form a complete cylindrical lining to the trachea. This was very soft, and could easily have been ejected through an artificial opening. An operation in this case might have proved instantly fatal, unless a sufficiently large opening had been made in the trachea to have permitted the easy ejection of the membrane. In two other cases, the autopsy had confirmed him in the belief that if an operation gave no better promise than of temporary relief, it were far better to run the risk than to abandon the case.

Dr. HUTCHINSON said he had seen the case in consultation, and, although he was aware that œdema of the larynx was rare in children, he thought the symptoms pointed rather to œdema than to false membrane. He had considered as pointing to this the peculiar hissing sound of inspiration, and the excessive action of the abdominal muscles. These facts, in connection with the extreme youth of the child, caused him to advise against an operation, inasmuch as recovery was very rare under four years of age. He recommended calomel in very small doses, without, however, expecting it to be of much service. The symptoms here were very similar to those of a case he had seen with Dr. John Ashhurst, Jr., in which there was œdema, and in which Dr. Ashhurst had operated with an unfortunate result.

Dr. ASHHURST said that the case to which Dr. Hutchinson had referred was one of œdema of the larynx, supervening during recovery from scarlet fever. The patient was a child about four years old, and, though almost moribund when seen by Dr. Ashhurst, Dr. Hutchinson and he thought it right to submit the question of opening the trachea to the parents, and, with their approval, to give the chance offered by the operation, which was attended with no particular difficulty, and which, though it certainly did not prolong life, yet scarcely, if at all, hastened death. With regard to the applicability of tracheotomy in cases of very young children, while Dr. Ashhurst could not endorse the rule laid down by some writers, that the operation was never justifiable in those less than four years of age, he regarded the prospects of a successful issue under such circumstances, particularly when the case was one of diphtheria or of pseudo-membranous croup, as extremely slight.

GLEANINGS FROM OUR EXCHANGES.

CANCER (*The Lancet*, March 21, 1874).—At a recent meeting of the Pathological Society of London, an interesting discussion took place on the subject of the origin and nature of cancer. Sir James Paget said that all that we see in the life of cancer naturally leads to the belief that the disease must from the first be more than a mere local tissue-change, and maintained the view that, though local in its origin, there is in some, possibly

in all, cases a predisposition to the disease which may be distributed through the system, but much more probably has its seat in some among the tissues of the body. We must hold both a local and a constitutional element as a necessary condition in every or nearly every case of cancer that comes under our observation. In the long group of diseases which we call cancers, there may be at one end diseases in which it is hard to discern any constitutional element at all, and at the other end, diseases in which the constitutional element far predominates over anything that we can suppose to belong to locality. We cannot overestimate the importance of inheritance in the origination of cancer, and it is not possible to conceive of the origin of cancer, or of any disease of the like kind, except by inheritance. In about one in three of all patients with cancer, the occurrence of the same disease in other members of the family is well known, and this number does not nearly represent what we may safely assume to be the predominance of inheritance in cancer. Of course, local diseases are also inherited, as in the cases of fatty or cartilaginous tumors, cutaneous cysts, malformations, etc.; but the contrast between inheritance of a local disease and inheritance of a constitutional one is very striking. When a local disease is inherited, it passes from progenitor to offspring in the same tissue, if not in the same place: we do not find cutaneous cysts growing in the stomach or testes of the offspring of those that have had them on their scalps. On the other hand, the transmission of cancer by inheritance accords perfectly with what we see in other constitutional diseases, as gout, syphilis, tuberculosis, and scrofula, the locality in each person being determined by some other circumstance than hereditary influence, which merely supplies the predisposition to the disease.

Next, if we watch the effects of injury in the production of cancer, we see very notably that it follows the same rule as it does in the production of others which we call constitutional diseases. Cancer sometimes appears, as the expression is, of itself; there is apparently so little provocation of it that we trace nothing that we can call an exciting cause. But in a very large number of cases it follows injury, and sometimes it follows so quickly that it is impossible to disconnect it from the changes which the injury has produced. Now, we know what is the limit of changes of structure which can be produced by injury in any person of sound constitution. The ordinary processes of repair, and the ordinary changes into which they may deviate without any constitutional condition being present, are as well known as are the ordinary changes of nutrition; and when, after injury, there is a deviation from these ordinary changes, we seldom or never entertain a question but that it is due to some constitutional defect in the person in whom it occurs.

This, therefore, is a second reason for maintaining in its fullest force the power of the constitutional element in cancer. Again, the same element is strongly marked in the constancy and in the method of its recurrence after operation or after complete excision. In ordinary typical cancer of the breast or any other part which is its frequent seat, the number of cases in which it does not recur is not more than one in five hundred, while not more than one in five hundred of the ordinary non-cancerous tumors ever reappears.

In the case of the so-called recurrent tumors, tumors which seem to stand between the cancerous and the non-cancerous, the very large majority reappear again, time after time. In one case such a tumor was removed eighteen times; but in the whole history of the surgery of cancers there is not a single case in which a cancerous mass was removed from the same part eighteen, or even eight, times, without the production of similar disease in the lymphatics and in the other organs.

* Meigs and Pepper, "Diseases of Children."

This recurrence has been referred to the mobility of cells, to their readiness to pass from one part to another; but in ostoid or scirrhus cancer the mass is very hard and dense, yet the disease is almost invariably propagated, while recurrent fibroid or cartilaginous growths are as soft, and are composed of cells and free nuclei as little held together, as in any of the softest forms of cancer, but do not, except in rare cases, propagate themselves.

Cancer is probably a blood-disease, because, as a constitutional disease, it is necessary to admit that it is all-pervading; and of the few tissues which are found in all parts of the body the blood is the one which, by analogy, we would expect to find the subject of disease. The objections which have been advanced to this theory are that a person may be cancerous and yet seem to enjoy perfect health; that in cancerous persons injuries may be inflicted and yet no cancerous change ensue; and that long intervals of health frequently exist between the removal of a cancer and the reappearance of another. All these objections, however, would apply equally to gout, syphilis, scrofula or tuberculosis, and all other constitutional diseases. It has been asked, how is it that, if there be the morbid blood in cancer, it should be more frequent in the female than in the male? This is easily answered. Cancer is eminently a disease of degenerated tissues. We are wholly misled if we suppose that cancer is a disease of healthy persons, whether by local degeneracy or general; it is essentially a disease of degeneracy, and increases in frequency in proportion to the number of persons living as age goes on. And the apparent exception proves the rule; for there are in women, without any correspondences in men, two organs which enter into degeneracy, closely corresponding with the senile, at a comparatively early period of life,—the breast and the uterus; and it is the predominance of cancer in the breast and uterus that alone makes the greater frequency of cancer in the female than in the male.

The great importance of considering cancer as a constitutional disease lies in the fact that, if we have any hope at all of curing it, it must be by constitutional remedies, as we have failed to cure it as a local disease for centuries past, and in hundreds of thousands of cases. We must hope that some day there may come to us a remedy as little expected, but not less sure, than was the employment of mercury in syphilis.

Mr. Arnott said that in relation to the manner of inheritance of cancer as compared with local diseases, as fatty, bony, or cartilaginous tumors, the difference exists because the latter are, for the most part, hypertrophies of a single tissue, and are not heterologous formations.

Sir James Paget had asked why we did not find a local recurrence in cancer as in those tumors which are called recurrent; and asserted that it was not anything in the physical attributes of the tumor, because scirrhus and osteoid cancers, which are excessively hard, are constantly and diffusely propagated. It may be said in reply that it is not the gross hardness or softness of a tumor which determines its diffusibility, but it is the distribution of its elements. We find that the mobility of the elements of a tumor stands in direct ratio to its malignancy, other conditions being the same. Thus, in glioma of the eyeball the cells are united only by a very diffuent creamy fluid, and accordingly we find that of all tumors glioma is one of the most malignant. In scirrhus carcinoma the cells lie loose and detached from one another, while in the recurrent tumor the cells are bound together by a grumous intercellular material, and therefore we do not find this latter tumor nearly so malignant as cancer, never affecting the lymphatic glands, seldom affecting distant parts of the system. So with other tumors. The *position* of tumors affects to a large extent their malignancy.

In proportion as that position is subjected to the conditions of warmth, of moisture, of great vascular supply, of free lymphatic connections, and of occasional exalted functional activity, do we find that the tumor is likely to be malignant. Admitting to the full that there is a constitutional something underlying the local appearances of cancer, we must admit at the same time that there is a similar or a somewhat analogous constitutional something underlying the simplest tumor; and if, by bearing this fact in mind, and taking into consideration with it the anatomical peculiarities of tumors, we are able to say that such a one should be malignant because of its anatomical peculiarities, or of its position, and that another will be innocent because of its anatomical peculiarities and position, then we need not be driven to search for any hypothesis of a blood-disease in the sense of syphilis or gout.

Sir Wm. Gull said that in dealing practically with malignant disease we may regard it as a local condition of the tissue then and there, however much the local development of it may have had to do with some inherited predisposition which we may properly term constitutional. If we could investigate the first beginning of cancerous change, and could take away the part, we should for the time rid our patient of the cancerous tendency in the particular part or place. Clinical observation shows that cases of operation in the eye, where defective vision is almost immediately recognized, have longer immunity from secondary cancer than cases of operation elsewhere.

Dr. Payne said that he supposed all persons were agreed in describing a growth as cancer when, whatever its minute character might be, it had already begun to infect or infiltrate a neighboring part. This infection or infiltration means that a change, or growth, or something which began in one tissue, has passed over from that part in which it originally began, to another which is adjacent to it and not of the same kind. Anatomically, one can give no better definition of cancer than that there is a kind of duality in its structure; that one part of the structure, looked at anatomically, is of one kind, and another part is at all events different, whether actually of another kind or not—another kind essentially. At all events, it is different in some respects. Now, this simple fact means that when any disease or change has once bridged over that very narrow but very important interval which separates tissues of one kind from tissues of another kind, it is almost as good as if it had already spread all over the body, because there is no longer in the whole course of its transmission through the body any barrier nearly so complete and incapable of being crossed as that which it has already passed.

A LUSUS NATURÆ (*Ohio Medical and Surgical Reporter*, January and March, 1874).—Dr. U. L. Huyette reports the case of a child born with a fluctuating tumor on its lumbo-sacral region, which was extirpated a few weeks after birth. Attached to the body of the child, with a perfect vascular and nervous connection, were a foot, leg, and thigh. The foot had three toes, with nails perfect, and on the thigh was a covering of down. The whole member measured about three and a half inches. There were also the rudiment of a hand, a small placenta, and three distinct sacs, which, together with the tumor proper, contained a fluid resembling the liquor amnii.

RUPTURE OF THE HEART FROM CONCUSSION (*Indian Medical Gazette*).—A man, æt. 23 years, was struck with the end of a *lathee* on the left breast, and died about two hours afterwards. There was no external mark of violence, but the cavity of the pericardium was completely filled with coagulated blood, and a fissure was found to exist in the wall of the left ventricle.

MISCELLANY.

· LAUGHTER AS A MEDICINE.—A short time since, two individuals were lying in one room, very sick, one with brain-fever, and the other with an aggravated case of the mumps. They were so low that watchers were needed every night, and it was thought doubtful if the one sick of fever could recover. A gentleman was engaged to watch over-night, his duty being to wake the nurse whenever it became necessary to administer medicine. In the course of the night both watcher and nurse fell asleep. The man with the mumps lay watching the clock, and saw that it was time to give the fever-patient his potion. He was unable to speak aloud, or to move any portion of his body except his arms, but, seizing a pillow, he managed to strike the watcher in the face with it. Thus suddenly awakened, the watcher sprang from his seat, falling to the floor, and awakened both the nurse and the fever-patient. The incident struck the sick men as very ludicrous, and they laughed heartily at it for some fifteen or twenty minutes. When the doctor came in the morning he found his patients vastly improved, and said he never knew so sudden a turn for the better; now both are up and well. Who says laughter is not the best of medicines? And this reminds the writer of another case. A gentleman was suffering from an ulceration in the throat, which at length became so swollen that his life was despaired of. His household came to his bedside to bid him farewell. Each individual shook hands with the dying man, and then went away weeping. Last of all came a pet ape, and, shaking the man's hand, went away also with its hands over its eyes. It was so ludicrous a sight that the patient was forced to laugh, and laughed so heartily that the ulcer broke, and his life was saved.—*The Sanitarian*, for May.

LIQUID GLUE.—*Colle liquide et inaltérable* is made by taking one kilogramme of glue, and dissolving it in one litre of water, in a glazed pot over a gentle fire, or, what is better, in the warm-bath, stirring it from time to time. When all the glue is melted, 200 grm. of nitric acid (spec. grav. 1.32) are to be poured in, in small quantities at a time. This addition produces an effervescence, owing to the disengagement of hyponitrous acid. When all the acid is added, the vessel is to be taken from the fire and left to cool. I have kept the glue, thus prepared, in an open vessel during more than two years, without its undergoing any change. It is very convenient in chemical operations; I use it with advantage in my laboratory for the preservation of various gases, by covering strips of linen with it.—Writer in *Comptes-Rendus* (1852), *Chemical Gazette*.

CREMATION OF THE DEAD.—The Communal Council of Vienna has adopted, by a large majority, the proposal of one of its members to establish in the cemetery the necessary apparatus for cremation, the use of which will be optional and open to all. A similar proposition is now being agitated at Grätz, which contains a population of 100,000.

ERICHSEN ON THE ELASTIC LIGATURE.—In a letter to the *Medical Times and Gazette*, Mr. John Erichsen characterizes the use of Prof. Dittel's elastic ligature as "simply a return to mediæval barbarism."—*New York Medical Journal*.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

IN two cases of advanced phthisis pulmonalis, I transfused about four ounces of lamb's blood, each time from a living three-months-old lamb. The syringe used was the modification of Aveling's Transfusion Syringe. Messrs. Tiemann & Co., New York, are getting up a syringe for me after the pattern of Dr. Hasse, Nordhausen, Germany, and which the latter uses only for transfusion of lamb's blood. The cases are so far benefited, but, being only two weeks old, it would be premature to give an opinion. I shall at some future time give a detailed article on the subject, and would recommend to your readers "Die Transfusion des Blutes," by Dr. Franz Gesellius, and "Die Lamm-blut Transfusion beim Menschen," by Dr. Oscar Hasse, Nordhausen.

The latter author has already transfused in thirty-seven cases, with decided success.

Very respectfully yours,
CARL PROEGLER, M.D.

ADDISON, ILL., 25th April, 1874.

GENERAL ORDERS }
No. 29. }

WAR DEPARTMENT,
ADJUTANT-GENERAL'S OFFICE,
WASHINGTON, April 8, 1874.

The following Joint Resolution of Congress is published for the information and government of all concerned:

"JOINT RESOLUTION authorizing the Secretary of War to detail a medical officer of the Army to inquire into, and to report upon, the causes of epidemic cholera.

"WHEREAS, epidemic cholera prevailed during the year eighteen hundred and seventy-three in various parts of the United States, especially in the valley of the Mississippi, causing a deplorable mortality; and whereas it is highly important that, whenever such epidemics occur, the facts concerning the spread of the disease and its mode of propagation should be ascertained as fully as possible, with a view to the prevention or limitation of future outbreaks; therefore

"Resolved, by the Senate and House of Representatives of the United States of America in Congress assembled, That the Secretary of War be, and he is hereby, authorized and directed to detail one medical officer of the Army, who shall, during the present year, under the direction of the Surgeon-General of the Army, in connection with the supervising-surgeon of marine hospitals, acting under the direction of the Secretary of the Treasury, visit the towns at which cholera prevailed during eighteen hundred and seventy-three, or such of them as in the opinion of the Surgeon-General and Secretary of the Treasury may be necessary, confer with the health authorities and resident physicians of such towns, and collect, so far as possible, all facts of importance with regard to such epidemic, and shall make a detailed report of the information collected on or before the first day of January, eighteen hundred and seventy-five, to the President, to be submitted to Congress. And the Surgeon-General is hereby authorized and directed to report to the Secretary of War, for publication, such information on the subject as he may have, or shall obtain."

Approved March 25, 1874.

By order of the Secretary of War:

E. D. TOWNSEND,
Adjutant-General.

Official:
Assistant Adjutant-General.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 28 TO MAY 4, 1874, INCLUSIVE.

McCLELLAN, ELY, ASSISTANT-SURGEON.—Relieved from duty at the Post of Lebanon, Ky., to enable him to comply with orders from War Department. S. O. 67, Department of the South, April 30, 1874.

GIRARD, A. C., ASSISTANT-SURGEON.—When relieved by Acting-Assistant-Surgeon Berkly, U.S. Army, to comply with orders received from War Department. S. O. 66, Department of the South, April 29, 1874.

SATURDAY, MAY 16, 1874.

ORIGINAL COMMUNICATIONS.

ON THE PRACTICAL IDENTITY OF TRUE CROUP AND DIPHTHERIA.

Read before the Philadelphia County Medical Society, Feb. 11, 1874.

BY BENJAMIN LEE, A.M., M.D.

HAYS'S *Journal* for January, 1870, contains a valuable and suggestive article with the following title: "Case of Diphtheritic Croup in which Tracheotomy was performed; Death on the Seventh Day from the Systemic Poison. By John H. Packard, M.D., of Philadelphia." At the close of the paper Dr. Packard says, "As to the cause of death. It is a very common opinion that the existence of false membrane in the bronchi or trachea is a strong contra-indication to operating, and that its absence is in favor of success. Yet in the case now detailed there was no such deposit found anywhere in the air-passages after death, although some casts were coughed up within the first three days. The child died from blood-poisoning; all that could be gained by the operation was gained."

"THE CHILD DIED FROM BLOOD-POISONING," or—as the doctor puts it boldly and distinctly in his title, thus distinguishing it from that blood-deterioration which results from deficient aëration—"FROM THE SYSTEMIC POISON."

My own belief is that in many, perhaps the majority of fatal cases of croup, the cause of death is *the systemic poison*, and that in all cases of croup our main chance of success consists in *counteracting* the systemic poison. It is in this belief that I offer the following remarks. At the time that I entered upon the practice of my profession in the city of New York, the medical mind was greatly agitated upon the subject of diphtheria, which had burst forth as an epidemic in several centres at the North and East, but nowhere so destructively as at Albany. A new disease to most of those who were thus suddenly called upon to confront it, they were naturally at a loss to know on what ground to meet it. Unfortunately, it was usually looked upon as a sthenic inflammation, and vigorously combated with antiphlogistics. That seductive little termination, *itis*, which so charmingly simplifies our pathological theories, supplying a bran-new, ready-made nosological nomenclature, with the very trifling expenditure of thought required in appending the same to the Greek (or, as was and is often ignorantly done, to the Latin) name of the organ or tissue which appeared to be most prominently affected in any given case or class of cases, was now most shamelessly married to one of its own family,—tacked on to the end of a morbid process,—and the resultant monster was diphtheritis, or an inflammation of a false membrane. The philological blunder we may pass over with a smile, but the pathological blunder which it expressed and the therapeutical blunder which it induced we can only look back upon with horror. The fatal char-

acter of those early epidemics is only too well remembered. But gradually light dawned. Some practitioners, empirically, simply seeking to avoid those remedies which at least produced no beneficial result,—others, on theoretical and rational grounds, tracing in the symptoms the general outline of a systemic blood-disease,—began timidly to pursue a supporting plan, and to seek for an antidote to the suspected poison. This was found in the salts of chlorine; and diphtheria speedily became the more manageable disease it is to-day. The analogy between the exudation of croup and that of diphtheria early attracted attention; but a still further analogy impressed me even more deeply,—that exhibited in the unhappily similar results of the same line of treatment,—viz., the depletory and depressant, the grandly-named antiphlogistic plan applied to the two affections. The mortality in both under similar arrangement was almost identical, and in this I recognized an argument for the identity of the morbid processes, and determined, when occasion presented, to test the matter by exhibiting in croup the class of remedies which had changed the whole complexion of diphtheria. The opportunity was some time in offering itself. In the course of perhaps a couple of years, having in the mean time had occasional cases of the latter disease to treat, I was summoned by telegraph to New Rochelle to see a child suffering under the former. Before leaving the city I fortified myself with a large phial of solution of chlorate of potassium, and a number of sulphate of quinine powders. The physician in charge was an elderly gentleman, of great intelligence, but who had for a considerable period retired from the active practice of his profession. The case was in the second stage, and, although not of the most intense grade, had progressed steadily, and as yet shown no signs of amelioration. The treatment had been thoroughly routine,—emesis by ipecacuanha, antiphlogosis by tartrate of antimony and potash, and defibrination by calomel. I concurred in its propriety, but suggested that it had already accomplished all that it could do, and that the time had perhaps arrived for substituting a supporting course. This was readily acquiesced in. I had the satisfaction of learning the next day that the symptoms already showed some improvement. The child recovered, happily. I would like in this connection to call attention to the formula which I employed for the preparation of the chlorate of potassium solution, as I doubt if it is in general use, and am confident of its superior efficacy:

R Potass. chlorat., ℥viij;

Acid. hydrochloric., ℥viij;

Rub together until greenish fumes of chlorine begin to rise, then add aq. cinnamom., f℥viij.—M.

S.—A tablespoonful every two hours.

This preparation contains chlorine, as will readily be seen, not only in its saline combination, but also free, and may be called the chlorinated solution of chlorate of potassium. It is the prescription of a British physician, whose name I unfortunately failed to preserve in appropriating his idea, and has cer-

tainly a peculiar potency, not only over diphtheritic processes, but in that troublesome, and just now frequent, form of throat-disease,—ulcerative tonsillitis,—the *herpes gutturalis* of Trousseau. I am well aware that a single case will not serve as a peg to hang a theory on, but it may answer for a text in connection with that first referred to. That I have never had another case of croup to treat is accounted for by two facts: the first, that I shortly afterwards withdrew from family practice; the second, that I invariably examine the throat of a child presenting febrile symptoms or acute disturbance of digestion, and attack every case of acute faucial congestion that offers itself, at the outset, with chlorate of potassium and quinine, carefully avoiding cathartics and depressants, and thus, as I believe, prevent the development of the diphtheritic poison. Had I, however, only my own meagre experience to adduce in support of the theory for which I am contending, I should be guilty of shameless presumption in airing it before a body at once so learnedly critical and so practically familiar with the facies of the affections in question. My design is rather to make use of the observations of those who have had larger opportunities and made a better use of them, in showing, first, that the analogy between these two diseases in every essential particular is so striking as to amount to a proof of identity, and secondly, that such an opinion is now steadily gaining ground among those who have most carefully studied them in their clinical as well as their pathological aspects.

Diphtheria may be defined in the light of the most recent investigations to be a zymotic disease, affecting the entire system through the presence, and probable multiplication, of a foreign living organism in the blood, having as a local manifestation an effusion of plastic coagulable material in the substance of the mucous membrane of the cavities of the mouth, pharynx, and nose, or an exudation of the same upon its surface. Its general symptoms are gradually increasing heat of skin and frequency of pulse, the latter rapidly becoming feeble, slight digestive disturbance beyond loss of appetite, and a degree of general prostration of the nervous forces quite out of proportion to the local lesion. In fatal cases, death evidently results from systemic poisoning. It is usually plainly epidemic, or contagious, or both.

As to its therapeutics, a system of depletion, whether by blood-letting, or active catharsis, or excessive emesis or profuse diaphoresis, or of contrast-stimulus by the prolonged use of nauseants, and notably of tartrate of antimony, is almost invariably followed by an aggravation of the symptoms, and, if persisted in, too frequently by a fatal termination. On the other hand, the free exhibition of an antizymotic, of which chlorine, either in solution or in composition with iron or an alkaline salt, appears to be the most deadly to this form of fermentative growths, and of bark or one of its alkaloids (of which quinia still stands *facile princeps*), a nourishing diet, and comparatively early resort to stimulus, will in the majority of instances conduct the case to a favorable issue.

Now, I claim that no one can take up a standard text-book on children's diseases, if the production of an author who holds the mirror fairly and squarely up to nature, instead of squinting at her through the crowquill of preconceived bias and prejudice, and read the description of these two diseases, without being struck with the close resemblance in their mode of invasion, progress, character of fatal termination, when not induced by immediate suffocation, and rate of convalescence. Even writers who believe croup to be a sthenic local inflammation are forced to admit that the febrile action is of a markedly lower grade than that which obtains in simple uncomplicated or spasmodic laryngitis. Thus, Meigs, than whom no one has described more faithfully the natural history of children's diseases, says, in treating of the differential diagnosis of these two last-mentioned affections, "The pseudo-membranous form of the disease is often preceded or accompanied by the presence of false membranes in the fauces, which is not the case in spasmodic, simple laryngitis; the symptoms of invasion of the former disease are *less acute* than those of the latter, the *fever being less violent* and the restlessness and irritability less marked than is usual in the simple affection, in which the general symptoms are severe from the first. The hoarseness of the voice and the cough follow a different course in the two diseases; the progress of these symptoms being slow and gradual in the membranous, and much more rapid in the severe spasmodic form. The fever is violent throughout the attack in the severe spasmodic disease, whilst in the other form it seldom reaches a high degree of intensity." He aptly describes the invasion of true croup as "*slow and creeping*." What means this "*slow and creeping*,"—this stealthy and masked—advance upon the citadel of life, but the development and diffusion throughout the body of a morbid material, gradually making itself master of all the avenues of approach? What has it in common with the bold onset of a frank, declared inflammation, such as an acute pleuritis or simple laryngitis? And how closely is it in relation with the prodromic period of most of the true fevers, and of diphtheria!

Bouchut, in his admirable work on children's diseases, entitled "*Traité pratique des Maladies des Nouveaux-Nés et des Enfants à la Mamelle*," unhesitatingly attributes to croup two of the essential characteristics of zymotic diseases,—first, that it does not ordinarily attack the same individual a second time, and secondly, that it is an epidemic disease; and, although he avoids committing himself unqualifiedly to a belief in its contagion, he considers it safer to separate children suffering under it from the healthy.

My impression, from consulting other authorities, is strong that these three traits of resemblance must all be admitted. So much, then, for the general family likeness existing between the two affections. Let us now consider the argument from therapeutics.

Prof. Fordyce Barker, of Bellevue Hospital Medical College, New York, in a communication addressed to Prof. A. Jacobi, on the "Treatment of Croup," which was published in the *American*

Journal of Obstetrics and Diseases of Women and Children, vol. iii. No. 1, May, 1870, boldly takes the ground that true croup and false croup are one and the same disease, differing only in the depth to which the tissues are involved, excluding the croup of diphtheria, which he considers a totally different affection. Entertaining, as I do, in addition to the sentiment of respect which the opinions of so conscientious an observer and so skilful a therapist as Dr. Barker command in the professional mind both at home and abroad, that sense of deference which a pupil must unavoidably carry with him through life towards a revered master, I still find myself unable, after a careful perusal of his paper, to accept the position which he here assumes. He appears to found it, although not perhaps avowedly, on the fact that the same remedy, administered at the outset, is, in his hands, equally efficacious in controlling both affections. This remedy is the "turpeth mineral," or yellow sulphate of mercury (*hydrargyri sulphas flava*); and the astonishing success which he has met with in its employment, never having lost a case of croup in the course of a long and intensely busy professional life, devoted in an unusual degree to the treatment of children's diseases, certainly entitles it to a most respectful trial. It must be borne in mind, however, to weigh honestly the value of this testimony, that Prof. Barker would call no case croup in which a particle of diphtheritic membrane had been observed upon the fauces. But, this aside, let us consider for a moment whether the agent which he employs does not possess properties which may render it of extreme value in both the simple spasmodic laryngitis and the diphtheritic infection. Everyone knows that prompt emesis is the one thing needful (to speak in a general way) to control and usually immediately relieve the laryngeal spasm.

Dr. Barker's reasons for preferring this particular means of emesis to all others in croup are the following: "It acts more promptly and efficiently than ipecac or alum; it is tasteless, and much more easily administered than either; it does not exhaust and depress the vital power like antimony; it is equally prompt in its action with sulphate of copper, while it is much more effective as a revulsive and sedative." He adds, "I think the active emesis from the turpeth mineral accomplishes the following results much more effectively and speedily than any other agent: it depletes the mucous membrane, by an abundant secretion of mucus which is thrown up; it removes from the larynx, by the forced expiration which it causes, any albuminous or fibrinous exudation which may be there in a diffuent state, and which by remaining may become subsequently pseudo-membrane; it acts as a powerful revulsive, and thus diminishes the capillary circulation in the trachea and larynx, and thus it becomes a most effective agent in arresting the inflammatory process."

But if an emetic is universally admitted to be the requisite in the spasmodic affection, not less general is the faith in its beneficial action in the diphtheritic or pseudo-membranous. And if we were called upon to sum up the characteristics of

an agent of this class which would best satisfy the requirements and present the fewest objectionable features in the latter form of disease, we could not do so more forcibly and succinctly than he has done in the above description of the properties of this medicament. But do its valuable properties as regards diphtheritic croup cease with its power of inducing prompt emesis? I think we are entitled to return a negative answer to this inquiry, on two grounds. First, that it is an active depurating agent in causing "so abundant a secretion of mucus, which is thrown up;" but, secondly and especially, because it is a sulphur compound, and sulphur is well known to be one of the most determined and destructive foes to the microzyme which the *Pharmacopœia* can command. Its efficacy in destroying the disease-germ present in spasmodic cholera can, I think, no longer be questioned, and it may be as potent over the micrococcus of diphtheria. May not the beneficial action of sulphate of copper, of sulphate of zinc, and of alum, the sheet-anchor of the elder Meigs, aside from their emetic properties, be reasonably attributed to the same component? And if so, do we not see an explanation of the superior value of the mercurial salt in the fact that mercury appears to possess to a more striking degree than any other mineral the *open sesame* to the circulatory and absorbent systems, obtaining admittance not only for itself, but for any remedy with which it may be for the time in the intimate companionship of chemical affinity,—a prompter entrance into the vascular system, and more immediate distribution throughout the body? May we not also read in the same light the happy results which have led the younger Meigs to place such confidence in the mild chloride in the management of membranous croup? Is he not administering that subtle and admirable antizymotic, chlorine, with a directness and efficacy perhaps even exceeding that with which many of us accomplish the same result in the exhibition of the much-trusted chlorate of potassium?

If the commencement of Dr. Barker's treatment appear admirably adapted to cut short a case of diphtheritic croup, however, not less appropriate is its continuation should the disease fail to be thus early arrested. Carbonate of ammonium as a vascular stimulus and promoter of mucous secretion, veratrum to shield the heart and vessels from excessive fatigue and fatal prostration, and quinia to sustain the nervous forces, constitute an armamentarium with which the practitioner might well feel himself tolerably equipped to meet a case of pure pharyngeal diphtheria. Nor must it be forgotten in this connection that all the preparations of cinchona have a peculiar potency in checking fermentation, while in sulphate of quinine we again have the sulphur element entering the problem.

Under the title of "Diphtheria in its Epidemiological, Nosological, and Therapeutic Relations," Dr. Max Jaffe, of Hamburg, presents, in *Schmidt's Jahrbücher* for July, 1873, a complete *résumé* of the periodical literature of this subject during the past four years. The first portion of the paper, that which discusses the epidemiological side of the question, is mainly taken up with the mode of com-

munication and pathological histology of the disease, and the histories of recent epidemics. Numerous interesting experiments in the way of inoculation of the lower animals with diphtheritic poison, on the part of Dr. Oertel of Munich, Letzerich of Braunsfels, and others, are rehearsed, especially with the view of determining whether "*in diphtheria we have to do with a merely local affection, or with a general infectious disease*,"—a question, as he well remarks, of the deepest import, as well for scientific inquirers as for the practising physician. The results are almost invariably in favor of the latter view, that which makes diphtheria a systemic disease with a local manifestation, not a local affection with a resulting disturbance of the general system. A constant microscopic element in the diphtheritic exudation has been found to be fungous growths of extreme minuteness and of immense numbers. These growths are classed as micrococcus or mykothrix. They are found not only in the diphtheritic membrane and in the mucous secretions, but also in great profusion in the blood, distributed through all the organs of the body, and even in the lymphatic vessels and glands. In some instances the lymphatics appeared to be entirely blocked up by them. Collections of these minute organisms were also noticed in the interspaces of the areolar tissue, and between the fat-cells. The kidneys appeared to be the organs to which they were more especially attracted, and in these their presence often coincided with a high degree of inflammation and microscopic extravasations of blood. The second division of the subject is devoted to the consideration of the "*Pathology and Anatomical Pathology*" of the disease, and it is to this portion that I especially desire to call attention.

Dr. Ludwig Letzerich, in an article "*On Exudation and Suppuration*" (croup and diphtheria), contributed to *Virchow's Archiv* (liii. 4, p. 493, 1871), after defining croup as a purely inflammatory process, and diphtheria as, on the contrary, caused by the deposit of a foreign fungous growth, which, piercing the epithelium, makes its way into the substance of the mucous membrane, and thus at the same time excites the diphtheritic exudation and provides for its escape,—while, I say, drawing this distinction carefully, he immediately after makes the following important admissions. First, that the diphtheritic membrane varies greatly in appearance, both under the microscope and to the naked eye, in accordance with the portion of the mucous membrane upon which it is found. On those mucous surfaces which are lined with smooth tessellated epithelium (as those of the mouth, nose, fauces, and vagina) it is usually strong and thick, and microscopically exhibits an abundant dissemination of epithelium-cells, either broken down or well preserved, and a greater or less quantity of pus-cells. On surfaces covered by ciliated or cylindrical epithelium (as the larynx, the upper part of the trachea, and the intestinal canal) it is softer and more creamy; the epithelium is completely eroded, and portions of the exudation appear, under the microscope, as mere masses of detritus, thickly strewn with fungous growths.

Second, that croup and diphtheria are developed together with extreme frequency, passing immediately into each other. Croup, he tells us, is very rarely developed with diphtheria of the mouth, nose, or fauces, but often—indeed, almost invariably—with diphtheria of the under surface of the epiglottis, of that portion of the larynx which lies above the vocal cords, in the lower part of the latter, and in the trachea. This striking fact of the co-existence of the two diseases he has had frequent opportunities of verifying by post-mortem examination. In one case the mucous membrane of the entrance to the larynx was completely destroyed by fungi, while that which lay below the vocal cords was scarcely robbed of its epithelium, simply overlaid with a very thin, creamy layer of diphtheritic exudation. The tracheal mucous membrane, on the other hand, from its commencement down to the bifurcation, was covered with a homogeneous croupal exudation, which was with tolerable ease removed as a complete tube. No fungous forms whatever were found in this cast, but a more or less regular stratification of the mass with pus-cells. The mucous membrane of the trachea retained its epithelium, freely strewn with puruloid cells, and its basal layer deprived of its ciliae, as in pure uncomplicated croup. Death ensued in this child from collapse, induced by the entrance of fermentative fragments into the circulation and the collection and reproduction of the fungi in the internal organs, especially the kidneys and spleen.

An essay delivered before the Medical Society of Berlin by Dr. Conrad Küster (reported in the *Berlin. Klin. Wochenschr.*, ix. 18, 19, 1872), on the Nature of *Diphtheria*, provoked a very animated discussion. He boldly took the ground that from the stand-point of the practising physician it was impossible intelligently to maintain the line of demarcation between these intimately-allied forms of diseased action. Diphtheritic and croupous angina, membranous, gangrenous, and false croup, he considered it impossible to hold as distinct diseases appearing together and running the same course of symptoms, simply and only because (and this perhaps for accidental reasons) the form of the exudation is different. Pathological anatomy explains the difference in showing that in the one case the exudation is superficial, and may then be thrown off as a membrane, while in the other it penetrates deeper into the tissues, producing necrosis, and thus leading to the formation of sloughs. In both membranous and gangrenous anginas we find alike, at the autopsy, diphtheritic sloughs or strongly adherent, deep-rooted deposits, without exception, in the fauces and pharynx and as far as the edges of the epiglottis, and, as we pass into the larynx down the trachea and into the bronchi, only membranous tube-casts, easily removable. We find there a complete mingling of the two forms, and are led to the inevitable conclusion that the character of the exudation is dependent upon the anatomical constitution of the locality in which it is thrown out.

Dr. H. Senator, while supporting the ordinarily accepted view of the distinct entity of the diseases

in question, acknowledged that he had never seen a true croupous inflammation and a corresponding true croupous exudation (a fibrous net-work with concentric layers of fibrin and pus-corpuscles) affecting the mucous membrane of the pharynx, either in diphtheria or any other affection, while, on the other hand, a croupal inflammation, under the influence of a diphtheritic infection in the true air-passages, that is, a diphtheritic croup, was an undoubted fact.

Dr. Lewin, in the *Berlin. Klin. Wochenschr.* and other journals, recognizes two forms of the diphtheritic process,—a protopathic, which attacks those mucous surfaces which are most exposed to the external air, is rarely accompanied by fever, often appears sporadically, and is very amenable to simple remedies; and a deuteropathic, which penetrates to the more protected cavities, is preceded by a prodromal fever, and gives every indication of systemic infection. This is the more purely epidemic form, and is extremely difficult to manage.

In regard to the question of the identity or non-identity of the “diphtheritic and croupous processes,” he holds that in their clinical relations they present a precisely similar configuration, have the same aggregate of symptoms, and consist of the same etiological elements, but anatomically are distinguished by the fact of being deep-seated or superficial. The cause of this difference, however, appears to lie only in the pre-existing histological characteristics of the membrane attacked,—diphtheria on pavement-epithelium, croup on ciliated epithelium; and the laryngeal croup, so often recognized as an independent affection, is therefore only to be regarded as a local manifestation of the diphtheritic process. In reviewing the history of medicine, Dr. L. recalls the fact that since the time of Bretonneau, who regarded croup as essentially laryngeal diphtheria, no author had undertaken to establish a distinction between the diphtheritic and the croupous processes until Virchow, and that even he did not desire to extend his pathologico-anatomical distinction to the clinical aspect of the disease.

Further, the results of treatment and the revelations of the autopsy agree in declaring that both processes may run their course simultaneously in one and the same individual. The purely histological distinction is thus set forth. In the larynx we find two sharply-defined histological regions, that of the pavement-epithelium, extending from the pharynx, along the lingual surface of the epiglottis, thence along its laryngeal surface, upon the false and the true vocal cords, and reaching nearly to the *macula flava*, and that of the ciliated epithelium in the lower regions of the larynx and the trachea. Closely corresponding with these tracts, we often find, in autopsies, the diphtheritic and the croupous processes separated from one another by this same boundary-line. More than this, during life the same differentiation can sometimes be made out by the aid of the laryngoscope. Similar observations may be found recorded by Virchow, Rindfleisch, and Wagner.

In support of the theory that laryngeal croup

only originates from the extension and descent of the diphtheritic affection from the pharynx, he adduces the following consideration. According to all reliable statistics, croup developed primarily in the larynx must be classed among the greatest of rarities. And even these few exceptional cases are often susceptible of other explanation. Diphtheria not seldom runs its course in the larynx unobserved; in those rare cases in which it has been unquestionably observed first in the larynx, it has in all probability taken its rise in the region of the pavement-epithelium, and finally, in cases where no laryngoscopic examination has been made, it is more than probable that a severe catarrhal laryngitis has, in consequence of the severity of its symptoms, been mistaken for laryngeal croup. In point of fact, catarrhal laryngitis may often, by a serous transudation, or a copious infiltration, or even a hemorrhagic extravasation into the areolar tissue of this portion of the larynx, induce a constriction of the glottis and simulate the tone and the dyspnoea of croup, without the presence of any croupal membrane.

In a treatise on “*Croup and Diphtheritis of the Pharyngeal Cavity, Exudation and Pus-Formation*,” Dr. Franz Hartmann, of Wiesbaden (*Virchow's Archiv*, liii. 2, p. 240, 1871), concludes that we are entirely unable to decide as to the “identity or non-identity of croup and diphtheria” from their clinical course, and that we must therefore refer to the development of the pathologico-anatomical processes for a solution of the problem. As regards the exudative process, every exudation has its origin in the vascular system, and consists of a coagulable fluid. In the production of the exudation, the capillaries and the lymphatics, which are closely connected by means of the so-called *serous* (juice) *vessels*, are both concerned. The anatomical arrangement of the mucous membranes is such that there is a possibility of the escape of plasma upon their free surfaces, and in diseased conditions this possibility becomes an actuality. In the pharyngeal cavity this escape of exudative material is favored by the firm compression of the mucous membrane, by means of strong muscular contractions. The primary exudation either coagulates at the spot where it is poured out, or flows down and coagulates below, constituting croup; but the subsequent exudation, in consequence of the muscles having to a considerable extent lost their contractility, is retained in the areolar tissue: that is diphtheria. The croupal exudation, therefore, always precedes the diphtheritic. Sometimes, in consequence of the inflammation being from the outset very acute, the muscular action is greatly interfered with, or even entirely suspended. We have then neither croup nor diphtheria, but angina, with or without abscess. It follows that in order to the establishment of the croupous process the inflammation must not be of a severe grade. He concludes, finally, that croup and diphtheria are not to be distinguished from each other, but are to be regarded as only different stages or grades of one and the same morbid process, no anatomical differentiation being possible.

Dr. Welsch, a physician practising in Kissingen, publishes several cases of croup and diphtheria occurring simultaneously in the same family, which, he considers, *establish the identity of the croupous and diphtheritic processes*, and refers to others which he met in the same neighborhood shortly after, as equally significant.

From the year 1868 to 1872, the north of Italy was the scene of a wide-spread and devastating epidemic of diphtheria, which reached its acme in 1871. So great were the alarm created and the interest excited by it that a committee of the most learned French and Italian physicians of the region was appointed to consider and investigate the subject in all its relations. This committee was unanimously of the opinion that the distinction between croup and diphtheria was one which could no longer be maintained, either from a pathologico-histological or a therapeutic stand-point.

In conclusion, I cannot summon to the support of my position a more powerful ally than Dr. Morell McKenzie, one of the highest British authorities on the larynx, whose opportunities of observation have not been greater than his powers of analysis. This writer, in his Jacksonian Prize Essay on Diseases of the Larynx, quoted by himself in the *British Medical Journal* of March 5, 1870, vigorously combats the doctrine of the distinct nature of these affections, on the following grounds: That neither is always, and both are sometimes, epidemic and contagious; that the exudation is essentially the same, being modified by its site, but presenting histologically no marked difference,—that of diphtheria having been noticed to become organized as well as that of croup; and that the sequelæ of diphtheria—albuminuria and impaired innervation—have also been observed to follow croup.

The opinions and facts just rehearsed, whether they carry conviction to the mind or not as to the point at issue, must be allowed to establish the fact beyond a peradventure that there is in Europe a large, respectable, and growing class of physicians who, however they may differ in their views of the mode of production of these two morbid results, and the accompanying pathologico-anatomical and histological changes and conditions, agree in holding that if not essentially they are at least practically, clinically, and therapeutically to be held as one and the same disease. And whether they are identical or not, this much must be allowed, that at the commencement of the attack so similar are the modes of invasion that no man can tell whether the case will prove to be one of uncomplicated or of diphtheritic croup. This was the fact in the case with the recital of which this paper opens. Fragments of false membrane were coughed up before any diphtheritic patches were seen upon the tonsils. In this view of the subject, then, remembering the deadly nature of the diphtheritic poison, does not prudence dictate that we should at once administer those remedies which experience shows to be antidotal to it and which can be of no injury should it not be present, at the same time withholding such methods of treatment as would be

contra-indicated by its existence? It will not do to wait until “the little one has become a thousand” and every arteriole and capillary is clogged with the sluggish, poisoned tide. We must destroy the germs before they have a chance to multiply.

I feel the less hesitation in urging a new departure in the management of this disease, so fearful alike in its course and in its termination, from the conviction that no plan can be suggested which will give more lamentable results than those which are universally acknowledged to follow that recommended by the systematic text-books.

A CONTRIBUTION TO OUR KNOWLEDGE OF THE VASO-MOTOR ACTION OF ERGOT.

BY H. C. WOOD, M.D.,

Lecturer on Diseases of the Nervous System in the University of Pennsylvania.

IN my work upon therapeutics I have given a sufficient summary of our knowledge as to the action of ergot upon the capillary system, and have shown that it is proven that the drug does cause contraction of the small vessels, but that it is as yet unknown whether that contraction is caused by an influence exerted upon the nerve-centres or is the result of a direct action upon the vessels themselves.

It is evident that this question is not one of merely scientific interest, but that it is very practical in its bearings, since, if the latter view be correct, much better results are often to be obtained by the local injection of the drug into the part to be affected than by its administration in other ways; whereas, if ergot acts only through the nervous system it is useless to subject patients to the inconveniences of these local injections. The present investigation has been undertaken to fill up the gap in our knowledge as to the action of ergot upon the capillaries; and, as it supplements the article in my general treatise, I shall say very little about what others have done.

My first experiments were directed to studying the effects of the fluid extract when injected into the cellular tissue. They were two in number; but, as they are in accord with those of numerous previous experimenters, I shall not give them in detail. In one of them $\frac{1}{3}$ iii injected at brief intervals, with $\frac{1}{3}$ ss into the femoral vein, served to raise the arterial pressure from 110–120 mm. to 117–125 mm.,—a rise which is very insignificant when compared with that produced by ergotin in experiments hereafter detailed; and it appears to me that the commercial fluid extract is much inferior and more uncertain than the commercial ergotin. The latter as used in the investigation was of two kinds or brands, resembling each other precisely, one being the preparation furnished by Powers & Weightman, the other that of Rosengarten; the physiological effects were identical.

In the following series of experiments ergotin was injected into the femoral vein.

Experiment III.—A stout young terrier.

TIME IN MIN. AND SEC.	PULSE.	ARTERIAL PRESSURE.	REMARKS.
0	150	85-90	Injected six grains.
1 m.			
1 m. 15 s.		20-25	
1 m. 45 s.		25-30	
2 m. 15 s.	135	60	
2 m. 30 s.		95	
3 m.		130-135	
4 m. 30 s.	96	150-155	
5 m. 30 s.	65	145-160	Injected 12 grains. Clot in tube.
9 m. 30 s.	95	125-145, mostly 130-140	
11 m.			
11 m. 15 s.			
12 m.	102	20-30	Beginning to rise.
12 m. 45 s.	111		
13 m. 30 s.		55-60	
14 m. 30 s.		105-110	
17 m.	63	140-150	Injected twelve grains.
27 m.		105-110	
27 m. 15 s.			
27 m. 30 s.		30-55	
28 m.		15-25	A general spasm.

29 m.		30-40	
31 m.		115-120	
32 m.			Injected twelve grains.
33 m. 45 s.		15-20	Injected four grains.
35 m.			
36 m. 15 s.		25-35	
37 m. 45 s.		55-60	
40 m. 31 s.			Injected twelve grains.
40 m. 45 s.		20-30	
41 m. 15 s.		13-17	
43 m. 45 s.			
44 m. 15 s.		35-40	Injected six grains.
49 m. 15 s.	135	80-90	
54 m.		80-90	

This experiment was repeated once with an exactly similar result, and is in exact accord with those of Dr. Holmes. The whole evidently prove that ergot injected into a vein causes an immediate almost instantaneous fall of pressure, and afterwards a very great rise; also that when enormous doses are employed the arterial pressure is permanently lowered. The most curious of these phenomena is the first fall of pressure; the points to be noted in regard to it are its suddenness and its brevity. Thus, in the detailed experiment, in fifteen seconds the pressure was reduced to one-fourth its original amount, and in ninety seconds was above normal. Expressed graphically, the effect of the first injection was as follows:

Dr. Holmes believes that this first fall is produced by a sudden spasm of the pulmonic capillaries, due to the intense action of the drug first precipitated upon them in overwhelming amount. It is perfectly conceivable, and, in fact, is almost self-evident, that such a spasm, by depriving the left heart of its

proper supply of blood, should lower very remarkably arterial pressure. It is, however, no less self-evident that if ergot, by being taken into the lungs, causes such a spasm as Dr. Holmes believes, the action of the drug must be a local one; for if the ergotic spasm is of centric origin, it can make no difference whether there is much or little of the drug in the lungs themselves. The cause of this sudden fall of arterial pressure is, therefore, best studied after it has been settled as to how the capillary spasm is brought about.

If the rise of pressure be due to a spasm which is centric in origin, paralysis of the vaso-motor nerves ought to prevent the rise of pressure. On the other hand, if the spasm be peripheral in its causation, due to a direct action of the drug upon the vessels, paralysis of the vaso-motor nerves ought not to affect it. As section of the cord high up causes vaso-motor paralysis, it is evident that the following experiments are decisive.

Experiment V.—A stout, plucky terrier. At 10.45 A.M. the cord was cut in the upper dorsal region, completely, as was verified by the autopsy. The first cardiometrical observation was one hour and a half afterwards.

TIME.	ARTERIAL PRESSURE.	REMARKS.
0	103-108	Injected twelve grains.
5 m.	95-100	
6 m.	20-33	
7 m.	25-30	
8 m.	40-45	
9 m.	60-65	
10 m.	75-80	
12 m.	95-100	
14 m.	105-110	Injected twelve grains.
21 m.	88-98	
22 m.		
24 m.	10-15	
24 m. 15 s.	20-25	Injected twelve grains.
26 m.	45-50	
31 m.	105-110	
33 m.	100-105	
44 m.	75-80	Dog killed.
60 m.	55-65	
61 m.	50-55	
64 m.	43-48	
67 m.	43-48	

Experiment VI.—A small but very strong and active terrier. The cord was cut completely, as verified by autopsy, in the upper dorsal region, and fifty minutes afterwards the first cardiometrical studies made.

TIME.	PULSE.	ARTERIAL PRESSURE.	REMARKS.
0	150	65-90; mostly above 80.	Injected twelve grains into femoral vein.
2 s.		35-40	
30 s.		Zero	
1 m. 30 s.	141	30-40	
5 m.	117	50-60	Injected twelve grains into the cellular tissue. Injected six grains into the femoral.
35 m.		75-95, mostly between 85 and 95.	
72 m.		Has been the same since last note.	
72 m. 30 s.		10	
75 m.		20-40	Injected twenty-four grains into the femoral artery. The respiration was momentarily suspended by the injection; now resumed, and pretty regular.
77 m. 30 s.	36	Directly after the injection fell to 10, then to 0, then vibrated between 0 and 10.	
80 m.		Since last note 5-15, now 0.	

These experiments certainly prove that after division of the cord, *i.e.*, after vaso-motor paralysis, ergot is powerless to raise the arterial pressure. The result obtained was verified by cutting the cord in animals already profoundly under the influence of the drug, when it was found that the arterial pressure fell to about its usual point in dogs who have suffered spinal section. Without going into more detail, it is obvious that these results not only prove that the vaso-motor spasm is centric in its origin,—a conclusion in accord with the experiments of Eberty upon frogs,—but also disprove Holmes's theory of pulmonic spasm.

In regard to the real cause of the primary fall, it is in the first place evident that it is owing to the sudden precipitation of an overwhelming dose of the ergot upon something, since, as I have frequently proven by direct experiment, it does not occur when the remedy is thrown into the subcutaneous tissue. The experiments of Eberty indicate very strongly that, when in sufficient amount, ergot acts as a muscle-poison to the heart, a conclusion which is strongly corroborated by the final result in my eighth experiment, in which, after the movement of the mercury and all arterial pressure were at an end, the respirations still went on with fair regularity; and the thorax having been opened, the heart was found not pulsating, but in a curious state of very active vermicular movement, irregular waves of movement continually running through it. *A priori*, therefore, it seems almost certain that the sudden fall is due to the whole dose being at once thrown upon the cardiac viscus, and that the rise occurs so soon as the concentration of the poison is destroyed by diffusion through the circulation. Further, as I have experimentally found that the fall is in no wise dependent upon the nerve-centres, but occurs after section of the cord and after division of the pneumogastrics, it appears to me very certain that the phenomenon is due to a direct action of ergot upon the heart.

If the rise of arterial pressure produced by ergot be due to centric spasm, it would seem as though injection of the drug into the carotid, *i.e.*, seemingly into the brain, ought to induce an immediate rise of the arterial pressure, followed by a fall when the heart felt the effect of the drug. It is very plain, however, that in such experiments as these we have a very complex problem; that the result is due to such a balancing of actions that any irregularity of circulation must produce a very disturbing effect. I have performed two experiments bearing upon the matter. They are as follows:

Experiment VII.—A stout terrier. All the injections made into the carotid, with Rosengarten's ergotin.

TIME.	PULSE.	ARTERIAL PRESSURE.	REMARKS.
0 12 m.	150	130-135 140-150	Six grains. Dog at once gave a brief convulsive and shuddering struggle.
12 m. 4 s.		185	
12 m. 8 s.		125-185	

TIME.	PULSE.	ARTERIAL PRESSURE.	REMARKS.
12 m. 15 s.		100-140	Twelve grains. No sudden rise followed.
12 m. 45 s.		60-85	
13 m.		90-120	
14 m.	150	150-160	
21 m.		145-150	
22 m.		20-30	Three grains.
23 m.		105	
26 m.	123	155-160	
46 m.	129	175-178	

Experiment VIII.—A very small terrier. Injections all practised into the carotid.

TIME.	ARTERIAL PRESSURE.	REMARKS.
0	110-145 Rose immediately to 165, and then almost at once fell down to 50 and below.	Four grains. Dog at once gave a howl, and convulsive shudder or struggle.
20 m.	110-120 Fell at once to 20, without previous rise.	Six grains. Dog quiet.
30 m.	130-135 After each injection no rise, but a fall from 110-80 to 60-40; pressure 15 sec. after each.	Injected, at intervals of 20 seconds, four injections of three grains each.

In these two experiments the results were strikingly similar: the first injection in each was followed by an instantaneous very decided rise of pressure, followed, after a very brief interval, by the usual fall; whilst the subsequent injections in no case caused a rise of pressure. Whether the first rise was directly caused by the drug, or was simply produced by the violent effort the dog made, must, I think, be considered doubtful.

A MILD CASE OF CEREBRO-SPINAL MENINGITIS FOLLOWED BY BLINDNESS.

BY CHARLES SHAFFNER, M.D.

THE following case is of interest on account of the unexpected and unfortunate sequelæ:

I was called on March 16 to visit Eugene H., a bright, chubby little boy, six years old, and apparently of good constitution, whom I found suffering with headache, tongue coated with a whitish fur, constipation, tendency to nausea, and high fever. He had been complaining with these symptoms for about four days, and soon grew worse, with severe occipital headache, rather marked retraction of the head, tendency to internal strabismus, which was fully developed in a week, but lasted only a few days, with equally dilated pupils; coat on tongue turned brown, no sordes, rather obstinate constipation, and tendency to nausea. I always found his lower extremities flexed. He had subacute tendinum, slight pains in arms and legs, but no convulsion, was very restless, sleepless, and slightly delirious at night, but in daytime was crabbed, and only desired to be let alone.

In two weeks he was convalescent, when we discovered that he was almost blind; he said, "I lost my eyes when I was sick." He then complained of pain over his eyes, and this, with some dilatation of the pupils, was all that called attention to the eyes.

He is now in full convalescence, but has only slight light-perception in both eyes.

Dr. Strawbridge examined the eye-ground, and found "choked disk," giving a diagnosis of impending atrophy of the nerve.

Dr. J. Lewis Smith, of New York, in his article on "Cerebro-Spinal Fever," in *Amer. Jour. Med. Sci.* for October, 1873, mentions, as sequelæ, strabismus, conjunctivitis, ulcer of cornea, cloudiness of cornea, and cataractous lens. There has never been any conjunctivitis, iritis, or keratitis in my case, and at present the media are clear, but the pupils still dilated. The hearing was also very imperfect for a few days.

The treatment was chiefly bromide of potassium and quinine, with citrate of potassium as a febrifuge. Calomel and rhubarb were used to relieve constipation. Sinapisms were placed on the extremities. He is now taking cinchona and iron, with cod-liver oil.

Dr. Albert G. Heyl made a careful ophthalmoscopic examination, and has made the following report: "On account of the age of the child, it was impossible to obtain a correct record of the amount of vision, or properly to estimate the extent of the paralysis affecting the muscular apparatus of the eye: the former, judging from the movements of the child, was considerably impaired.

"There was no ptosis. Both recti externi were paralyzed, especially the left, giving rise to marked internal strabismus on that side. The third nerve on the left side was also implicated, as was evidenced by the left cornea occupying a higher position than the right. Both pupils were widely dilated. Media perfectly clear. In the right eye hypermetropia $\frac{1}{2}$, in the left hypermetropia $\frac{3}{4}$, existed. The fundus of each eye presented a marked example of the 'choked disk': the distinct swelling of the papilla, its clouded, reddish appearance, the radiating stripes along the course of the nerve-fascicles, and the dilated and tortuous retinal veins, were all sufficiently pronounced in character to render the diagnosis easy. There were no ecchymoses. The apex of the left papilla was best defined with a +10; that of the left, with a +12."

TRANSLATIONS.

ENDOSCOPIC EXAMINATION OF THE URETHRA AND BLADDER.—Dr. J. Grünfeld, an assistant of Prof. Sigmond, of Vienna (*Wien. Med. Presse*), being struck with the fact that the results from the use of the endoscope in the diagnosis and treatment of diseases of the urethra have not been commensurate with those attained by the use of the laryngoscopic mirror, sought to devise some simpler form of apparatus than the instrument of Désormeaux and its modifications. He finds that he can make satisfactory examinations of the urethra by means of an ordinary catheter with some modifications, to which he gives the name of urethro-scope. In the construction of this, two objects have to be borne in mind: the instrument must bear a proper relation to the individual peculiarities of the case, so as not to injure the organs under examination, and provision for adequate illumination must likewise be made. Instruments, therefore, of varied form will be needed, but they are all made of metal, blackened upon the interior, and provided with a funnel-shaped expansion at the end which is exterior to the urethra.

The simplest form and the one which is available in the largest number of cases is a straight tube, the end of which is closed with a plain plate of glass. This should not be placed vertically to the axis of the tube, but at an angle, so that the rays of light used for illumination will not be thrown back from it. The tube of the instrument must be carefully oiled before introduction. Dr. Grün-

feld uses for illumination either sunlight or that of an ordinary argand lamp, throwing the rays of light into the funnel-shaped end of the tube with the ordinary laryngoscopic mirror, which he employs either upon the forehead or in preference held in the hand. The mucous membrane of the urethra can be examined from the meatus urinarius to the orifice of the bladder, and by thrusting the tube still farther onward the surface of the posterior wall of the bladder itself comes into view, and by moving the instrument different fields of view are obtained. He uses also a second form of the urethroscope which is not so available for making examinations as for topical applications, in which the end of the tube is not shut in by a plate of glass. When this is to be introduced, a conductor must be first placed inside the tube, as without this precaution the operation causes pain. In these two forms of the instrument the mucous membrane of the urethra is presented to view in the funnel as a cone with folds converging to the centre of the field of view. Pressure excited at the edges of this tube may give rise to some disturbance in the capillary circulation, and thus cause some change in the natural color of the mucous membrane. To obviate this pressure and consequent source of error, a third form of the instrument was devised, in which the end of the tube is closed, and at a short distance from the end there is a window in the side, closed with a plate of glass. Beneath this there is a small mirror at an angle of forty-five degrees, so that the light may be reflected parallel to the axis of the tube. There is also a fourth form, in which the catheter is curved, the window being made upon the convexity of the curve. These windows can be made of plain glass, or of glass which has been ground to correspond to the convexity of the catheter. The catheter employed corresponded to Nos. 18, 22, and 24 of Charrière's scale. The examinations are best made with the patient lying upon the back, with the thighs flexed; but if the outer half of the urethra is to be examined, the patient can be in a standing posture. This simple apparatus certainly presents many advantages over the complicated machinery of the endoscope; the special illuminating facilities are not required, and the introduction of the catheter is not so painful to the patient.

W. A.

FR. MOSLER (*Berliner Klin. Wochenschrift*) thinks that the introduction of large quantities of fluid into the intestine is advisable under the following conditions, in addition to those suggested by Simon: 1, in dysentery, when, after the irritating discharges have been washed away, solutions of a disinfecting and astringent character may be introduced; 2, to increase the amount of bile in various forms of icterus, and also to favor its expulsion; 3, to wash out any remains of tape-worm that may remain after its partial expulsion, and also for the removal of seat-worms. In the latter case he advises the addition of half a tablespoonful of benzine to every two pints of fluid used.

W. A.

CAUSES OF CRÉTINISM.—Dr. Klebs has made a number of observations with the object of ascertaining, if possible, some at least of the causes which go to produce crétinism in certain districts of Switzerland.

A series of analyses of the water used for drinking-purposes in different localities, compared with the comparative frequency of the disease in such places, seems to indicate the presence of a large percentage of the sulphates of calcium and magnesium as having an undoubted influence in causing the affection in question. —*Archiv f. Ex. Path.*, Feb. 1874.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 16, 1874.

EDITORIAL.

DENTISTRY.

THE amount of angry comment which the little birds of whom Solomon speaks have brought to our editorial sanctum, concerning an article on oral surgery that appeared some time since in our columns, has astonished and, we may add, amused us. The most plausible explanation is to be found in the fact that the members of the profession supposed to have been slighted really know that they are laying claim to a position for dentistry which it does not at present deserve, and which the world does not grant. A condition of extreme general peripheral sensitiveness marks the existence of a spinal or centric nervous weakness in the moral as well as in the physical world, and nothing is so inducive to the production of this weakness as the knowledge that we are claiming or pretending to what we do not possess. The real duke laughs when he is taken for a commoner, but the shoddy duke flies into a passion. When any one knows he is right, he is usually tolerant of discussion. In this innate sense also lie, we suppose, the sources of the self-laudatory speeches which are so abundant at dental conventions. The true Hercules does not deem it necessary to be always proclaiming his strength, or the man of robust health to be constantly telling his friends that he is well.

Whether our explanation of the exceeding sensitiveness of our friends the dentists be or be not correct, the fact remains that dentistry is not looked upon at all by the medical profession as in

the slightest degree co-equal with medicine, that the degree of *doctor* of dental surgery is viewed with a great deal of amusement and a little vexation, and that the claim that dentistry is a branch or specialty of medicine is generally met by internal cachinnations, whatever external behavior the laws of politeness may enforce. These may be hard things to hear, but we hope our dental friends will not be angry; they are not the opinions of the *Times* or of its editors, but are the simple facts of the case,—facts which it behooves those who wish to see dentistry placed upon a higher plane to recognize.

We are not now speaking of dentists, but of the dental profession. There are many dentists of the highest culture and of the most worthy social characteristics, precisely as there are such men in all of the higher walks of life; but certainly, even if dentistry in the abstract is worthy of a position as a medical specialty, the living, concrete dentistry can only gain such honor by a complete reorganization of the profession.

The dentist formerly acquired his art in the office of his predecessor, and it was not considered necessary for him to study in any more extensive sphere. As time went on, and the lucrateness of the calling attracted more and more able and cultured men, aspirations rose higher and higher; dentists began to demand a more extensive education, and the dental colleges were founded. But now another step is being attempted, and a claim is put forward for a recognition of dentistry as a medical specialty.

In considering this claim, the great difference between dentistry and such real medical specialties as ophthalmology must not be lost sight of. In the first place, dentistry originated, or at least has grown up, entirely outside of the medical profession, whilst the true specialties have originated and been cultivated solely inside the profession. In the second place, dentistry constantly asserts itself as something outside of the medical profession, whilst the specialties do not. Every dentist announces himself as such upon his door-plate or window-sill, whilst a ban is laid upon the man who labels himself in the same way as an oculist or an aurist. In the third place, the dental profession is saying to the world day in and day out, by its actions, that a general medical culture is of no use, or at least is not a necessity to the dentist, whilst the specialist insists that before special studies are undertaken the candidate must have had a thorough general medical education.

The dental colleges have been a great aid to the dental profession, and, indeed, whatever claim den-

tistry really has to be called a profession rests almost exclusively upon their labors. Yet they are an insuperable bar to its ever becoming a medical specialty, and the degree of D.D.S. is the badge of a partial culture which must shut out from the medical ranks every one who wears no other insignia,—a fact of which the dentists seem painfully aware, since so soon as any one of them takes a degree in medicine the D.D.S. disappears in a twinkling from door-plate and window-shutter. So long as the dental profession, by their deeds, say that such half-culture is all that is necessary for a dentist, why should the members complain if the world and the *Times* agree with them and assign to dentistry the position which it at present holds?

There is only one way by which a higher position can be achieved, and the first step is the abolition of the dental colleges and an enforcement of the idea that a general medical education must precede the special one. If we are correctly informed, at a recent meeting in New York, Dr. Robert Arthur, a prominent dentist of Baltimore, proposed that students entering the specialty should graduate in medicine and afterwards pursue special studies under suitable instruction, or else that the student should select such schools as afforded, during the summer, special courses of lectures, and other facilities for studying dentistry.

The latter seems to us a most happy idea, and, if dentists are to be doctors, the plan suggested is the most feasible. It appears to us that it would certainly be to the interest of the medical schools to offer the facilities; and although, as stated in a previous editorial, we do not perceive the necessity for this general culture in those who practise dentistry, and doubt the possibility of enforcing any expensive education upon the students, yet it may be that on trial we shall be found to be mistaken. This much we can assure our friends the dentists, that just so soon as they comply with the universally adopted rules of the medical profession, and measure up to its standard, that profession will receive them with open arms,—not because they are dentists, but because they are doctors.

THE little town of Brives, in France, has experienced a sad calamity, in the form of an epidemic of syphilis. During last year it was found that many women recently confined were affected with a strange disease, which was soon recognized as specific. When the nature of the malady was discovered, the town was almost convulsed with domestic disturbances,—husband against wife, wife

against husband, family against family, as men and women strong in their own innocence accused each other of infidelity to the marriage-bed. The number affected was quite large: fifteen women, nine husbands, and ten children are known to the authorities, whilst many, it is believed, have concealed from the world their infection, physicians of eminence asserting that they knew of such cases. After a time of great disturbance, the cause of all the trouble was found to be a midwife, who had contracted a chancre upon her finger in the discharge of her duties, and had carried the poison from house to house. After the discovery the moral thunderstorm subsided, and nothing of evil, beyond the wrecked victims, remained.

THE human intellect passeth human understanding. If it reaches up almost to the infinite, so does it sink down to the infinite,—science and folly, twin brethren, dwelling in that wonder of wonders, the human brain. The nearest approach to the infinite of folly we have as yet met with is in some specimen pages of Allen's Encyclopædia of Homœopathic Materia Medica; the provings of aconite yielding some two thousand symptoms, including accurate visions of friends hundreds of miles away.

A TELL-TALE STRAW.—Among the prizes at a recent homœopathic Commencement was a hypodermic syringe. Another straw.—In the journal to which we are indebted for the above information we notice the advertisement sheets chiefly occupied by Tilden & Co.'s price-list of their pills and granules. "As honest as a homœopath" bids fair to become a proverb.

CORRESPONDENCE.

THE following is an extract from a letter to the editor, written at Breslau, East Prussia, by a highly-gifted physician now pursuing his studies abroad. It was not written for publication, but has been so entertaining to the editor that he has thought it would interest the readers of the *Times*.

BRESLAU, EAST PRUSSIA, April 9, 1874.

Among the men that most interested me in Berlin was Virchow. He is the best lecturer that I have ever heard. His utterance is clear, language simple and elegant, manner usually quiet, but at times animated, and, with the exception of a little drawl now and then, his elocution may be said to be almost perfect. He gives one the impression that his thoughts and words

come freely and abundantly, and that all he has to do is to *pour* out his ideas in any style that he sees fit. Indeed, he talks in very much the style that his Pathology is written (it reads much pleasanter in German than in English), and this is more noticeable in his lectures on *General Pathology*. His skill as a speaker is no doubt very much dependent upon his duties as a member of the German Parliament, which, unfortunately for the students of pathology, keep him very busy. He lectures three times per week on Special Pathology and four times on General. The lectures on Special are supposed to begin at nine A.M. and last till eleven, but, as he is never punctual, they are very much shorter. His irregularity has caused a great deal of dissatisfaction among the students, and one morning that he was later than usual they filed out of the room as he appeared at the door. That was an extraordinary thing for such decorous creatures to do. The Pathological Institute has been lately refitted, and the room devoted to his morning lectures is lofty, well lighted, and handsomely painted in distemper. The arrangement for the students is a very convenient one: it enables all to see, and each in turn to examine the specimens without trouble. The form of the table you may get from this enclosed diagram. Along the front

edge of the table is a little railroad-track, three or four inches wide, and sunk two inches below the surface. The wooden trays holding the specimens are readily fastened by a few turns of a thumb-screw to little brass platforms with grooved wheels which fit this track, and can be easily pushed along from one student to another without taking too much attention from the lecturer. In one corner of the room is a platform, upon which he stands, having at his left a large movable (elevated or lowered) blackboard, and at his right a sort of side-board, convenient for small preparations. His use of the blackboard is constant, and from long practice his drawings are easy and skilful, and are a great help to his lectures. There is an elaborate description of this lecture-room in the *Berliner Wochenschrift* (I don't remember the number). If you want a good nap after listening to Virchow, go to Frerichs's auditorium. It is on the second floor of the hospital building, and is a long

low room capable of seating about one hundred and fifty students, the seats rising one above the other towards the back of the room, and it opens at one end into the wards, and at the other into a hall-way where are hooks for students to hang their coats and hats. The room is usually full, and, it not being well ventilated, the air in a few minutes becomes almost suffocating. Happily, the "academic quarter" cuts his lecture-hour down to forty-five minutes. His station is in the centre of the little arena between the rows of seats and the folding-doors leading into the wards. A few feet from him on either side are usually seated in a semi-circle a number of doctors, who, together with the students, always rise with great ceremony when he enters. A patient in bed is wheeled or carried in from the neighboring ward, and, addressing the student whose turn it is to appear in the arena, he begins. He speaks in a low, melancholy tone, and rarely raises it, so that after a while it becomes very monotonous. His manner is languid, and his enunciation (to a foreigner) very indistinct. It seems to be a great effort to him to talk, and even when he makes his examinations his motions are slow. Now and then he condescends to a witticism, and the rustle with which his auditors receive it, and which breaks the "awful quiet," has something *solemn* about it. Precisely at twelve he ceases. The student to whom his remarks have been addressed has the privilege of following the case to its termination,—of entering the wards day after day to note condition, treatment, etc., till either recovery or death.

Traube, whose lectures upon diseases of the chest were very interesting, is a far better speaker than Frerichs. Although somewhat older than the latter, he has much more vivacity. He keeps his ears closed with cotton, in order (it is said: I can't vouch for it) to preserve his acuteness of hearing. And he believes in Selters Wasser with warm milk to relieve the cough of phthisis and pneumonia. This remedy, by the way, is very much used, and if the milk is of the right temperature—not too hot, nor lukewarm—it is quite agreeable. I have tasted it repeatedly. Some persons object to it at first, but gradually acquire a liking for it. Are you interested in the surgical clinics? At Langenbeck's you will find everything, from the pulling of a tooth up to the resection of joints. It is a very poor clinic for every one but the student who is called into the arena. The professor has so many assistants that only now and then can a good view of the patient and operation be obtained, and, besides, the course and result of the case are not observed by the students. Bardeleben's clinic is better. This is in a large new brick building in one of the quadrangles of the Charity Hospital. It is a two-story building, with four wards, and a corridor on each story. The upper story belongs to Bardeleben, who has also an auditorium off the corridor, and the lower story to Wilms. The latter, by the way, is said to be the most skilful operator in Germany. Bardeleben meets the students in the wards at 8.30 A.M., and they make the rounds with him. The dressings are removed and renewed in their presence, and he com-

ments or calls their attention to practical points as he passes from patient to patient. At ten he enters the auditorium, and patients for operation are brought to him. This is called his lecture on operative surgery. At eleven he makes a pause for about fifteen minutes, during which the room is cleared, and a blackboard is brought in, and then he lectures till twelve on the science of surgery. Is not that admirable? And all this takes place every day. He is a firm believer in the antiseptic treatment of wounds, and the method of Lister is carried out with great exactness. Here also in Breslau at the surgical clinic the method is employed, but not with the same care. They here use the warm bath as a hygienic measure with greater frequency and regularity than I have elsewhere seen. For instance, a man suffering from pyæmia was daily placed for fifteen or twenty minutes in a warm bath, and always appeared brighter and better for it; and this was continued up to the day of his death. It was employed without any reference to his temperature, etc. For the reduction of temperature in surgical cases quinine is firmly believed in. As an illustration, Dr. Viertel, Prof. Fischer's house-surgeon, showed me the temperature-table of a patient who had been brought in suffering from a severe contused wound of the left hand, in which sloughing took place. On the day after admission his temperature rose from 38° (Celsius) to 40° (about 105° Fahrenheit). He received at night two grammes (about thirty grains) of quinine dissolved in water, in divided doses,—i.e., he took half the quantity, and then in half an hour after the remainder. The next morning the temperature was 37.5°—nearly normal. In three or four days there was another rise to 40°, and the dose was repeated. Again the temperature fell to 37.5°, and never rose above 38° after that, but has remained at normal 37° ever since. This was the sixteenth day after admission, and the wound was nearly healed. I don't attach much value to that as an observation, for I don't know the condition of the wound, etc., on the days of elevated temperature, but the case was shown to me as an illustration of the power of quinine, and so I give it to you. I am surprised at the amount of clinical material in this city. It is a university town of only 171,000 inhabitants, and yet they have a large hospital containing nearly one thousand beds, besides a number of others of from one hundred to two hundred beds belonging to "deaconesses" and "sisters" and "brothers" of various orders. Very many of the patients come from the province of Silesia, and that may account for it. The mortality also is *very satisfactory*, for there are about three post-mortems per day, and an abundance of pathological material. Cohnheim is the Professor of Pathological Anatomy. At present he is out of town, seeking, in a change of air, relief from a troublesome laryngitis. It is whispered that he has phthisis. It is too bad, for he is a very enthusiastic teacher. Did you know that Rindfleisch had left Bonn and gone to the University at Würzburg? The Vienna people are looking for some one to take Rokitsansky's place. They made a big offer to Von Recklinghausen, which

he refused, preferring to remain at Strasburg. They offered him 12,000 gulden (\$6000) per annum, a share of the students' fees equal to about 4000 gulden more, also to build him a new and complete Pathological Institute, and to give him four or five assistants.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held February 11, 1874, at 8 o'clock P.M.

THE PRESIDENT, DR. W. L. ATLEE, in the chair.

Dr. WASHINGTON L. ATLEE called the attention of the Society to a little instrument in frequent use by the physician and surgeon,—viz., THE CAUSTIC-HOLDER. After having tried every form of holder, including hard rubber, found in the shops, and having one after another destroyed by the corroding influence of the daily use of nitrate of silver, he had Mr. Gemrig to construct one, under his directions, of platinum and gold, which answered an admirable purpose. This instrument defied the destructive action of the caustic. But still there was one defect in common with all caustic-holders,—viz., *after using up the stick of caustic there still remained in the grasp of the holder a small end that could not be conveniently utilized, and was necessarily wasted.* Frequently, in attempting to remove this remaining portion from the holder in order to substitute it by a longer piece, it would crumble up, and many of the particles would remain strongly adhering to the instrument, requiring a loss of time properly to remove them. Generally, however, these waste ends were removed without breaking them, on doing it immediately after the holder was used and before it had time to dry. Having occasion to use a large amount of solid nitrate of silver, these waste ends accumulated to a very great extent, and, as they were too costly to throw away, he endeavored, by several methods, to utilize them. He finally adopted the following simple plan,—viz., *a piece of hard rubber was melted (like sealing-wax) over a flame, and the end of a lead-pencil charged with a small portion of it. The caustic was pressed on this while still soft, and in a few moments the bond of union was perfect, and the holder ready for use.* He soon found this holder economic to the greatest degree, as it enabled him to use up even the smallest particles.

For office use Dr. Atlee has several of these holders charged with different-sized pieces of caustic, from the smallest fractions to pieces two and three inches long. In using these holders the caustic itself will break rather than separate from the cement. After using up the caustic, it will be found that the rubber will have become deteriorated and unfit for further use. It must then be melted and wiped from the handle, and a fresh supply added. For pocket use Dr. Atlee still uses his old platinum holder, but in a different way. He places in its grasp a cylindrical piece of wood about one inch in length, to which he seals the caustic in the way above stated. He took from his pocket his caustic-holder and exhibited it, stating that he had just returned from a journey of twenty-three hundred miles, and that the attachment still remained unbroken.

Dr. Atlee stated that he had such an unlimited and extended experience in the use of this holder that he could recommend it without hesitation as the most simple, the most satisfactory, and the most economical instrument in use. He has used no other for

the last fifteen or sixteen years. During this period he had repeatedly brought the plan to the notice of his brother-practitioners.

The doctor brought with him several holders, such as he uses in his office, in order to exhibit them to the Society. They were brought here already charged, as he was in the habit of using them. But upon taking them from his pocket and unwrapping them he found the longer pieces of caustic broken. On examination, however, it was noticed that they had not separated from the bond of union. Some of these holders were ordinary pen-holders, and sticks of similar character.

He said that he would now instruct them how to make a holder; and, pulling from his pocket a hard rubber ring-pessary, he remarked that he would startle the members of the Society by stating that he would now show them the best use, as a general rule, to which it could be applied. Heating a part of it over the gas-light until it was softened, he then charged the end of a stick with a small quantity, sufficient to form a bond of union between it and a piece of caustic, and pressed the latter against the charged point. It soon hardened and formed a firm union. He purposely gave it an angular inclination, to show that with his simple plan any direction can be given to the caustic to suit the convenience of the operator, which he thought was an additional advantage over every other instrument.

Dr. ATKINSON said he hoped that Dr. Atlee would at an early day give his views as to the employment of pessaries. He thought the gentleman did not entirely discard them.

Dr. B. LEE then read a paper on the "Practical Identity of True Croup and Diphtheria."

Dr. HAMILTON said that notwithstanding the ability shown by the lecturer in endeavoring to render positive, or at least probable, the identity of diphtheria and croup, the evidence in opposition to this view he regarded as so definite and strong in character as to be wellnigh or quite irrefutable. A few clearly-marked points of divergence may be mentioned. Croup prevails occasionally in an epidemic form; but even here the more frequent attacks can generally be referred to some appreciable exciting cause in close relation with a peculiarity of the season or state of the weather. In diphtheria many severe epidemics have occurred where this relationship, if it existed at all, has scarcely been noticed. The number of persons attacked in an epidemic of croup, whether in a community or in a family, is small when compared with what frequently happens in diphtheria, so that the latter is found to be in many cases beyond all comparison more destructive in its progress than is ever witnessed in the former disease. To effect this result we may perhaps rationally assign, as the causative influences, contagion, and some peculiar telluric and atmospheric condition of an occult character. The prominent symptoms in croup are local, succeeded, of course, in violent or fatal cases, by systemic disturbances indicative of an untoward issue. In diphtheria, constitutional symptoms are, as a rule, first observed, and continue throughout the attack, whilst, significantly enough, in some cases the local affection is but slightly developed, or wanting. The croupal condition of the respiration noticed in some attacks of diphtheria is explained by the anatomy and physiology of the parts invaded; yet a severe and wide-spread epidemic must be admitted to exert an influence upon other co-existent disease. Whilst there are no special sequelæ to croup, diphtheria, on the contrary, is in this respect pre-eminently conspicuous in the paralyses which have attended some epidemics of the disease, affecting sometimes twenty-five per cent. of those attacked. Albuminous urine in croup is exceptional; in diphtheria it is common, indicating an essential difference in the pa-

thology of the two diseases. Other points of divergence may occur to and be expressed by members.

Dr. J. COLLINS agreed with Dr. Hamilton that there was a difference in the two diseases. The fact that we had abandoned treatment did not show that it was otherwise. He had heard Dr. Keichline say that many years ago he had used chlorate of potassium and tonics. He himself was very fond of sulpho-carbolate of zinc topically. He uses the sulpho-carbolate of zinc in the strength of $\frac{3i}{\text{to}}$ $\frac{3i}{\text{for}}$ for the throat-trouble; and in gonorrhœa two to five grains to the ounce. The doctor questioned the propriety of the word "orthodox."

Dr. LEE agreed with Dr. Collins that the word "orthodox" in the connection in which he had employed it was liable to misconstruction, and thanked that gentleman for the opportunity of making an explanation in regard to it. He intended to describe by it neither the opinions nor the practice (especially not the latter) of individual members of the profession, or even of the great mass of the profession,—the active working practitioners of the day,—but rather that traditional lore which is handed down from generation to generation in our systematic text-books. Every writer of a system of medicine or surgery has a thorough knowledge of some one branch or department to which he has given special attention. On this subject he speaks from experience, and his teachings are practical and useful. On all others he but reproduces, often unintentionally, the dicta of his professors, or copies from the systems of others. Wishing to make his work an enduring monument to his fame, he must mould it into a grand symmetry. He must have a central theory around which everything must crystallize, to which everything must conform. Such stubborn facts as cannot be made to square exactly with his preconceived plan must be kept out of sight or explained away, and hence the mass of the volume becomes partisan and misleading. Leaving out of view the exacter fundamental departments of anatomy, physiology, chemistry, and materia medica, he doubted whether the influence of such works was not, on the whole, injurious. He was confident his experience was not singular, that much that he had learned in his student-days he had been obliged to unlearn as he found himself face to face with disease. It was an open question in his mind whether it would not be better to place in the hands of the student earnest practical monographs than to cram him with these sifted compendiums which aim to do all his thinking for him.

Dr. ATKINSON thought that monographs by the masters in the profession were far preferable to the voluminous text-books. He believed that if the valuable papers read before this Society were published in pamphlet form it would reflect credit on the Society and be made to pay.

GLEANINGS FROM OUR EXCHANGES.

RETENTION OF URINE (*Medical Record*, March 2, 1874).—Dr. S. Fleet Speir reports a case of retention of urine from enlargement of the prostate, occurring in a man æt. 64. Repeated attempts at catheterism having failed, the bladder was emptied by means of an aspirator, and this operation was repeated fifteen times without causing the slightest discomfort or injury. Internal urethrotomy was performed, although there was no genuine stricture, and was followed by the introduction of a catheter, which, after some difficulty caused by obstructing mucus, was found sufficient to empty the bladder. Dr. Speir calls attention to the great accumulation of mucus that may take place in

the bladder after repeated tapping with the "aspirator." The upper portion of the urine is usually drawn off (the patient lying upon the back), and there is a constant accumulation or deposit of mucus and salts at the bottom of the bladder; and in cases of vesical irritation or inflammation it may become *very dense and tenacious*, obstructing the eye of the catheter and giving rise to the suspicion, on the part of the surgeon, that his catheter has not reached the bladder, or that there is but little urine present, when in fact the reverse is true, and all that is needed is a sufficient force to compel the thick mucus to pass. In cases where repeated tapping is likely to be needed, the bladder should be injected through the tube of the aspirator, and the fluid withdrawn again by the same means, thus preventing the accumulation of mucus.

RESEARCHES ON THE EFFECT OF FOOD ON THE COMPOSITION OF THE BONES.—H. Weiske and E. Wildt (*Zeitschrift für Biologie*, 1873, Band ix. Heft iv. p. 541), in a series of investigations carried on upon goats last year, showed that although the withdrawal of lime or of phosphoric acid from the food of adult animals led to fatal consequences, yet that it had little or no influence on the composition of the bones, and, in particular, did not make them more friable. The present series of researches was made with a view of determining whether any such influence was exerted on the bones of young animals. The animals selected on this occasion were Southdown lambs, about ten weeks old. One of these was fed upon food poor in phosphoric acid, a second on food poor in lime, and a third on normal diet. After the lapse of fifty-five days, various bones were analyzed, and the general result was, that just as in adults so in young animals: no remarkable change was produced in the composition of the several bones by the difference in the diet, or, in other words, the composition of the bones is independent of the nature of the food. The bones were, however, stunted in their growth.

DRAINAGE IN CHRONIC CYSTITIS (*Virginia Medical Monthly*, April, 1874).—Dr. Hunter McGuire reports a case of chronic inflammation of the bladder, of eight years' standing, in a woman *æt.* 41 years. He introduced a piece of fine gum tubing, perforated at the end, and allowed it to remain in the bladder for six weeks, it being withdrawn only for purposes of cleansing, or for the substitution of new pieces in place of the old. During this time the patient was kept in bed, and the urine collected in a urinal; but at the end of that time the free end of the tube was fastened to a gum bag which was attached to the patient's thigh. She wore the tube for about four months, constantly improving. When it was withdrawn, she had at first complete incontinence of urine, but the bladder gradually recovered its power, and a complete and permanent cure resulted.

VOMITING AND HÆMATEMESIS FROM CONSTIPATION (*The Lancet*, March 28, 1874).—Dr. Ogle reports the case of a hysterical girl, in whom obstinate and almost constant vomiting, with profuse hemorrhage, was found to depend upon constipation. Under the use of purgatives—calomel and jalapin—and small doses of sulphate of magnesia, with enemata and suitable mild diet, all symptoms by degrees disappeared, the pain being greatly relieved by hot spongio-piline saturated with laudanum applied to the abdomen, and the vomiting by hydrocyanic acid draughts.

RESECTION AS A REMEDY FOR ABDUCTION OF THE GREAT TOE, HALLUX VALGUS, AND BUNION (*Medical Record*, April 15, 1874).—Dr. A. Rose details a number of cases in which resection was performed, and concludes therefrom that resection of the head of the first

metatarsal bone for abduction of the great toe is a safe operation, when, as after-treatment, submersion in warm water is adopted.

Resection is equally safe as, and furnishes a more useful limb than, amputation.

Resection in old and obstinate cases of hallux valgus is to be preferred to orthopædic appliances.

Finally, resection, properly made, leaves the limb without apparent mutilation, and in a condition as useful as the healthy and sound foot.

STRICTURE OF THE URETHRA (*New York Medical Journal*, April, 1874).—In concluding a long and able paper on "Urethrotomy, External and Internal," Dr. Fessenden N. Otis makes the assertions that stricture, as ordinarily met with, is absolutely within the reach of curative measures; that if completely divided, and this division maintained until healing of the parts has occurred, no recontraction can ever take place; and that the division of stricture is not more hazardous, to say the least, than rapid, permanent, or even temporary dilatation.

He says stricture may be present before difficulty in urinating occurs; it is always present when gleet is present,—gleet, as a rule, meaning stricture. Dilatation of strictures is, at the best, but a temporary expedient,—valuable in close stricture when urination is interfered with and dividing-instruments cannot be introduced; but dilatation is not only without permanent value, except in such cases, but it is pernicious, inasmuch as, while it is never curative, it takes the place of curative measures. He concludes by asserting that nothing short of complete division of strictures can ever result in radical cure.

GONORRHOEA, GLEET, ETC.—We have recently known a number of very obstinate cases of gleet relieved by the introduction of a catheter, smeared with mild zinc ointment, once or twice per day. Many recent cases of gonorrhœa are much relieved by the same means, with the addition of a little carbolic acid, sulphate of zinc, or nitrate of silver. An injection containing about two grains of sulphate of zinc to the ounce of water, and the whole made thick as cream with finely-powdered golden-seal (*Hydrastis Canadensis*), is deemed worth from \$500 to \$1000 by those who have been very speedily cured by it. At least, such is their verbal estimate of its value. It is thrown into the urethra, and allowed to remain as long as it will.—*Medical Times and Gazette*.

FOREIGN BODY IN THE BLADDER (*Medical Record*, March 2, 1874).—In removing a piece of glass tube from the bladder by perineal section, Dr. George C. Smith resorted to the ingenious device of coating the jaws of the forceps with molasses candy, thus securing adhesion and protecting the glass from fracture, and also, the candy being soluble in the urine, not leaving behind any nucleus for future calculus.

THE LOCAL TREATMENT OF CARBUNCLE (*The Lancet*, March 28, 1874).—Peter Eade, M.D., strongly recommends the local use of carbolic acid in carbuncle. He has employed a solution of one part of the acid in four or five of oil or glycerin, and in those parts with which it came in actual contact it had a marked beneficial effect, retarding the circumferential spread and checking or aborting the carbuncular inflammation.

CHLORAL IN TETANUS (*Indian Medical Gazette*, March 2, 1874).—Dr. John Meredith reports a case of traumatic tetanus successfully treated with chloral hydrate, rest, quiet, and nourishment. The chloral was given thrice daily, in twenty-grain doses, and seemed to control the spasms effectually.

MISCELLANY.

THE BURGLAR AND THE SKELETON.—A "skeleton in the closet" is not generally considered a pleasant thing to have, but a recent occurrence in Greensburg, Pa., shows that it may sometimes answer a good purpose. A burglar broke into a physician's office in that town, and, opening a closet (while his companion with a dark-lantern was in another part of the room), got his hands between the jaws of a skeleton, which, being adjusted with a coil spring and kept open with a thread, closed suddenly on the intruding hand by the breaking of the thread. Startled at being thus seized, he uttered a faint shriek, and when his companion turned the lantern towards him and he beheld himself in the grim and ghastly jaws of Death himself, he became so overpowered by fear that he fainted and fell insensible to the floor, pulling the skeleton down upon him, and making so much noise that his companion fled immediately. The doctor, alarmed at the noise and confusion, hastened into the office, and secured the terror-stricken burglar, still held by the skeleton.

STUDYING FOR A PROFESSION.—A young independent New Englander, who had an eye on No. 1, was studying for the ministry in one of the one hundred and eight theological schools in the United States, and when about to graduate he found out that this was one of the worst-paid professions, as people in general care more for their bodies than for their souls, so at the nick of time he changed his mind, and studied medicine in one of the ninety-two medical colleges. When almost through this very useful course of training, he discovered an important fact, namely, that people care more for their pockets than for their bodies, or for anything else. This settled the matter for him; he again changed his mind,—this time definitively: he went to study law.—*Manufacturer and Builder.*

RABIES AND HYDROPHOBIA.—Two fatal cases of hydrophobia are reported in the *Sheffield Daily Telegraph*, both occasioned by bites from a cat. One case, that of a female domestic servant, aged thirty-two years, occurred in this wise. While engaged in toasting some bread on Christmas day, the cat attacked her, fastening upon the left hand, and the animal was dislodged with difficulty. The day following Christmas day, the same cat attacked a man, wounding him, and he died of hydrophobia on the 22d of January. The young woman first bitten did not manifest symptoms of hydrophobia until the 29th of March, and she died on the 31st.—*London Lancet.*

DR. DAWSON has sold his proprietorship of the *American Journal of Obstetrics* to Wm. Wood & Co., of New York, and is to be succeeded by Dr. Paul F. Munde as editor. Dr. Dawson offers an annual prize of \$150 gold, the first subject being "Congenital Deformities, and Diseases depending on Maladies of the Uterus or Membranes." The competing essays must be sent to the publishers (Wm. Wood & Co., 27 Great Jones Street, New York) of the journal on or before

April 15, 1875. The names of the authors must accompany the manuscripts in sealed envelopes, as usual with prize papers.

SPECIMENS of glycerin in crystals were exhibited at the Vienna Exposition. Such a form of this article had been previously considered impossible. When perfectly pure, however, it is said to crystallize readily, and once in a solid state it does not melt except at a high summer temperature, and the liquid thus formed will not re-crystallize on cooling. The process for its preparation is patented, and a secret. In the form of crystals, glycerin is of use only as a chemical curiosity.—*The Tennessee Pharmacal Gazette.*

ACTION OF HUMAN MILK ON PUPS.—M. Depaul refers to the hurtful action of women's milk on pups. He had a bitch which, having pups and sickened, a nurse applied them to her breast, trying to keep them alive, but they wasted and almost died. He has frequently seen instances of the same happen where pups were applied to the breasts to try and elongate the nipple, an application which is often supposed to be a most efficacious method.

THE DRUG BUSINESS IN GERMANY IS WELL GOVERNED.—There is a central organization with nineteen districts, and each has a director. Each district has five circles with a sub-director. Each circle consists of about fifty members, with a circle-president who watches over the members. No chance for irregularity.—*The Druggist.*

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 5 TO MAY 11, 1874, INCLUSIVE.

ABADIE, E. H., SURGEON.—Leave of absence extended sixty days, on Surgeon's Certificate of Disability. S. O. 101, A. G. O., May 8, 1874.

BAILY, E. J., SURGEON.—Relieved from duty in Department of California, and to report in person to the Commanding Officer, Department of the Columbia, for duty as Medical Director of that Department. S. O. 96, A. G. O., May 2, 1874.

COOPER, GEORGE E., SURGEON.—Relieved from duty in Department of the Columbia, and to report in person to the Commanding General, Department of California, for assignment to duty. S. O. 96, c. s., A. G. O.

WRIGHT, J. P., SURGEON.—Relieved from duty in Department of Dakota, to proceed to Carlisle, Pennsylvania, and, on arrival, report by letter to the Surgeon-General. S. O. 96, A. G. O., May 2, 1874.

TOWN, F. L., SURGEON.—Relieved from duty in Military Division of the Atlantic, and to report in person to the Commanding General, Department of Texas, for assignment. S. O. 96, c. s., A. G. O.

WEEDS, J. F., SURGEON.—Assigned to duty at Fort Abraham Lincoln, D. T. S. O. 83, Department of Dakota, April 29, 1874.

TILTON, H. R., ASSISTANT-SURGEON.—Relieved from duty in Military Division of the Atlantic, and to report in person to the Commanding General, Department of Texas, for assignment. S. O. 96, c. s., A. G. O.

BROWN, J. M., ASSISTANT-SURGEON.—Relieved from duty in Department of Texas, to proceed to Philadelphia, Pennsylvania, and, on arrival, report by letter to the Surgeon-General. S. O. 96, c. s., A. G. O.

DE HANNE, J. V., ASSISTANT-SURGEON.—Relieved from duty in Department of the Missouri, to proceed to New York City, and, on arrival, report by letter to the Surgeon-General. S. O. 96, c. s., A. G. O.

WOODRUFF, E., ASSISTANT-SURGEON.—Relieved from duty in Department of Dakota, to proceed to Louisville, Kentucky, and, on arrival, report by letter to the Surgeon-General. S. O. 96, c. s., A. G. O.

DICKSON, J. M., ASSISTANT-SURGEON.—Relieved from duty in Department of the Platte, to proceed to Cincinnati, Ohio, and, on arrival, report by letter to the Surgeon-General. S. O. 96, c. s., A. G. O.

SATURDAY, MAY 23, 1874.

ORIGINAL COMMUNICATIONS.

ON LIGATURES: AN ATTEMPT TO DECIDE ON THE BEST MATERIAL FOR THE LIGATION OF ARTERIES.*

WITH EXPERIMENTS.

BY JOHN R. HAYNES, M.D.,

Philadelphia.

"Quod si illa quoque profluvio vincuntur, venæ quæ sanguinem fundant apprehendendæ, circaque id, quod ictum est, duobus locis deligandæ, intercidendæque sunt, ut et in se cœrent et nihilominus ora præclusa habeant."—CÆLUS, De Re Medicâ, lib. v. cap. 26.

THE plan of this essay comprises a brief sketch of the history of the ligature and its introduction into surgical practice, and an account of the three great classes of ligatures, the *thread*, the *metallic*, and the *animal*. From each class a typical material will be selected for more particular examination and experiment, including *silk* (representing thread), *silver* and *lead* (metallic), and *catgut* (animal ligatures). Finally, an endeavor will be made to indicate which of these substances is best adapted to the wants of the practical surgeon.

HISTORY OF THE LIGATURE.

The practice of surgery previous to the introduction of the ligature presented few inducements to one of tender or fastidious nature. Not the least of its horrors was due to the want of some efficient means of checking hemorrhage. Applications of the actual cautery or some form of the potential cautery, as buttons of vitriol, boiling turpentine, pastes of arsenic, etc., were the principal means employed; but so worthless were they that surgeons feared to perform even unimportant operations, lest death from hemorrhage should result. To avoid this direful termination, injured members were seldom amputated until mortification had ensued, and were then removed by incisions through the dead parts. By some, a large knife, heated to redness, was employed, with the hope that the cauterization would close the vessels as soon as they were divided. Fabricius ab Acquapendente, the tutor of the illustrious Harvey, was in the habit of removing diseased breasts by means of a sharp piece of wood or horn, dipped from time to time in aqua fortis. Guido di Caulico, who flourished at the end of the fourteenth century, amputated limbs by surrounding them with so tight a band that they ultimately dropped off. Well might ancient surgery be termed "a horrid trade."

In the writings of Celsus, who lived in the first century, we find the first mention of the ligature. He gives explicit directions for tying wounded blood-vessels.

The first operation for aneurism was performed by Rufus of Ephesus, about the middle of the second century. The tumor in this case was situated

at the bend of the elbow, and had been caused by a wound of the vessel in venesection.

According to Aetius, who wrote in the sixth century, the ligature was sometimes used in cases of wounds and aneurisms. This author gives the first description of what is known as the operation of Antyllus, for the relief of aneurism.

But no evidence exists to show that the ligature was used in any save exceptional cases. That its application to operative procedures, except occasionally in aneurism, was unknown, is proved by the frequent references made to other methods of checking hemorrhage. Indeed, after the time of Aetius, it seems that it was scarcely ever used, even in wounds and aneurisms. In illustration of this fact, it is related that Albucasis, a celebrated Arabian surgeon, who flourished about the beginning of the twelfth century, refused to amputate the hand of a patient, lest he should die of hemorrhage, and that the sufferer, with commendable courage, performed the operation himself, and survived.

In 1564, the immortal Ambrose Paré re-introduced the ligature, which he had been led to use, he thought, "by the special favour of the sacred Deitie; for," he continues, "I learnt it not of my maisters, nor of any other, neither have I at any time found it used by any." But the surgeons of that day were too well pleased with their hot irons and their caustics to listen to him. Nor did his defence against the malignant attacks which the publication of his invention called forth, in which he spoke of the brief and unsatisfactory references made to the ligature by the ancients, produce a greater effect. Strange to say, the ligature was not employed at all during the next century and a half, and then we find it commencing a very slow progress. Thus, in 1707, among all the surgeons to the Hôtel-Dieu, Dionis was the only one to employ it. In 1739, Heister, the famous German surgeon, recommended its partial use only; while in England, so late as 1761, Mr. Sharp, surgeon to Guy's Hospital, complained that "the ligature was not received with that universal acceptance one would wish and expect."

Since the ligature has come into general use, it has not been free from the attacks of those seeking to introduce new methods of arresting hemorrhage.

Thus, acupressure, first described in 1859, was intended by its inventor, Sir James Y. Simpson, to supersede the ligature. But the latter has not lost its hold on the confidence of the great majority of surgeons, and acupressure is now used only in rare and exceptional cases.

The systematic twisting of arteries to arrest hemorrhage, technically called torsion, has a few enthusiastic advocates at the present day. First mentioned in the works of Galen, this method was revived by Amussat in 1828, and thoroughly tried by him and other great surgeons of that day. After long experience, the celebrated Velpeau came to the conclusion that it was "not so universally applicable as the ligature, and in no case did it possess any advantage over it." It is possible that torsion may come into frequent use as a means of checking hem-

* An Inaugural Essay for the degree of M.D. in the University of Pennsylvania, to which the Alumni Prize was awarded at the Commencement held March 12, 1874.

orrhage from the smaller arteries after operations; but as applied to the larger arteries it is generally considered untrustworthy, while the fact that it causes sloughing of the portion of the vessel twisted removes much of its claims to superiority over the ligature. One great objection to torsion consists in the difficulty of performing it. Thus, Prof. Agnew states that he has seen Mr. Thomas Bryant, of London, spend ten minutes in twisting a single vessel;* while Billroth,† of Vienna, frankly states that he has entirely failed in attempts at torsion in cases of excision of the breast, and that, in his hands, secondary hemorrhage was on one occasion the consequence of unskilful torsion of the posterior tibial artery.

It is unnecessary in this connection to enter into a detailed description of the numerous instruments that have been brought forward with the intention of supplanting the ligature to a greater or less extent. Among them are Assalini's compressor, Nunneley's forceps, Richardson's tubular compressor, etc. The artery-constrictor of Dr. S. Fleet Speir seems to be the most ingenious and reliable of these contrivances; but even this has not obtained any great degree of favor among surgeons.

Although all of the above methods of preventing hemorrhage or obliterating arteries have advocates here and there in the ranks of the profession, yet it cannot be gainsaid that the ligature, from its great safety and the ease with which it can be applied, deserves its place as practically the best hemostatic that has yet been invented.

CHANGES WHICH ENSUE IN AN ARTERY AFTER LIGATION.

A. Ligation of an Artery in its Continuity.

I. When a thread is applied firmly to an artery—

(1.) The internal and middle coats are divided as if by a sharp knife. The external tough fibrous coat is puckered, and its surfaces internally made to touch each other; in this position it serves to keep the edges of the divided coats in contact. The vasa vasorum of the external coat are obliterated by the pressure of the ligature, and the constricted ring of tissue, therefore, deprived of nourishment.‡

(2.) Lymph is poured out from the edges of the divided coats above and below the ligature, and they become firmly adherent.§ On this is deposited, in the cardiac cul-de-sac, fibrin from the blood,

which rapidly grows until it forms a conical mass, reaching to the first branch given off; it does not at first adhere to the sides of the vessel, but merely by its base to the button of lymph. In the distal cul-de-sac of the vessel, as a rule, no coagulum is formed; nor is the deposit of lymph in this situation so great.|| Lymph is poured out from the external coat and the sheath of the vessel, forming a mass which envelops the noose and knot of the ligature.

(3.) The constricted portion of the external coat ulcerates, or sometimes separates in the form of a minute slough, and, together with the ligature, is gradually extended through a minute orifice in the capsule of lymph enclosing the ends of the vessel.¶ The place of the cast-off portion is filled in with lymph, so that dissection does not reveal any break in the continuity of the cord.**

(4.) The coagulum becomes adherent to the internal surface of the vessel, and undergoes organization, causing the arterial tube to be obstructed up to its first branch.

(5.) Absorption takes place, and after an interval of two or three months nothing remains of the vessel, from the point ligated to the first branch given off on the cardiac side, but a fibrous cord.

(6.) A small tortuous canal, uniting the ends of the artery, becomes developed in the centre of the fibrous cord.

This curious fact was first pointed out by Maunoir, of Geneva. He applied two ligatures to the carotid artery of a fox, and divided it between them: on

|| *Changes in the Distal Cul-de-sac of a Ligated Artery.*—"In the distal cul-de-sac of the artery, I have never seen any very distinct coagulum formed either in the human subject or in dogs on which I have experimented, but merely small detached fragments of coagula and some plastic effusion." (Erichsen's System of Surgery, vol. i. p. 254.) That secondary hemorrhage occurs most commonly from the distal extremity, does not show the importance of the clot, but of the adhesive inflammation of the internal coats, which is more apt to be imperfect in that situation. Were the absence of the clot the cause of hemorrhage, that accident would occur in nearly every case of ligation in the continuity of an artery; for, as we have seen, in nearly every case the clot is absent. Farther on will be noticed Porta's experiments on the "slack ligature," which also tend to prove the same assertion; since he found that hemorrhage with this kind of ligature was very common, no opportunity being allowed the internal coats to take on adhesive action; while with the ordinary tight ligature hemorrhage was unknown. The very shape of the clot shows that it is not designed for the prevention of hemorrhage. It is generally conical, and does not touch the sides of the vessel for a long interval,—not till the vessel is beginning to contract in calibre.

¶ *Division of the External Coat.*—"The ligature divides the internal and middle, but only compresses the outer coat. It makes a slough of a little piece of the latter, and when it comes away, at the end of ten days or a fortnight, you find the slough in it." Brodie's Lectures on Surgery, p. 306.

* A ligature takes from ten days (brachial artery) to twenty-one days (common iliac) to separate. Hence, as a general rule, sufficient time is afforded nature by the internal inflammatory changes, to glue the edges of the vessel together, and, by the external formation of a capsule, to form a splint to press them together, and thus occlude the artery and prevent hemorrhage.

** Mr. Jones's description of the changes in the ligated artery is so graphic that a portion is subjoined: "The formation of the coagulum is of little consequence; for, soon after the application of the ligature, the extremity of the artery begins to inflame, and the wounded internal surface of its canal, being kept in close contact by the ligature, adheres, and converts this portion of the artery into an impervious and, at first, slightly conical sac. It seems to be entirely owing to the effusion of lymph, by which this adhesion is effected, that the coagulum of blood formed within the artery is sometimes found adhering by a small portion of its base to the extremity of the artery. But whilst the adhesion of the internal parietes of the artery is accomplished, a considerable quantity of lymph is effused between its coats and among the parts surrounding its extremity, so that in a very short time the extremity of the artery is enveloped in lymph, and covered with a layer of it, just as we have seen the punctured artery to be. After a short time the ligature occasions ulceration of the part, around which it is immediately applied, and, acting as a tent, a small aperture is formed in the layer of lymph effused over the artery. Through this aperture a small quantity of pus is discharged, as long as the ligature remains, and finally the ligature itself also escapes, and the little cavity which it has occasioned granulates and fills up, and the external wound heals in the usual manner." Pp. 160-161.

* Lecture on Hemorrhage, Course 72-73, at University of Pennsylvania.

† Schmidt's Jahrbücher, No. 4, 1872.

‡ Bell compares the constricted external coat to a strangulated portion of intestine. Principles of Surgery, vol. i. p. 220.

§ *Adhesion of the Divided Coats.*—"The union between the edges of the divided coats is often found to be quite firm in experiments on the lower animals twenty-four hours after ligation (Jones on "The Processes employed by Nature in suppressing the Hemorrhage from Divided and Wounded Arteries." London, 1805, p. 140). That firm union sometimes takes place in as short a time in man, is proved by the results of the temporary ligature, which will be discussed in a succeeding page.

¶ That the adhesive inflammation of the divided coats is the most important portion of the process is demonstrated by the experiments of Jones. In many cases, after the ligature had separated, the artery was found entirely destitute of coagulum. Thus, in describing the appearances forty-nine days after ligation, he says, "The tunics of the artery were remarkably thick, but there was no coagulum within it." (*Op. cit.*, p. 155.) In many cases where the coagulum did exist, it was non-adherent, and, therefore, useless in preventing hemorrhage, as in Exp. IX., p. 148, where the animal was killed nineteen days after the application of a ligature, and, on examination, the artery was found to be obliterated by lymph, and containing "a black coagulum, which did not adhere to its internal surface."

examining the parts, a long time afterwards, he found "a very small vessel, a millimetre in diameter," joining the extremities of the artery.* Mr. Jones cast a great deal of ridicule on this observation, but it has been fully confirmed by Stilling and Porta, the latter giving a beautiful illustration of the "direct anastomosing vessels."†

The quantity of pus formed around the artery when the process of closure takes place in the most healthy condition of the tissues, is very small. Indeed, suppuration may be entirely absent, the strangulated portion being absorbed, as sometimes happened when it was the custom to cut the ligature short and leave it in the wound. On the other hand, pus, instead of lymph, may be poured out around the vessel at the point of ligation, and the ends of the artery lie bare in the cavity of an abscess. In such an event, secondary hemorrhage is sure to occur, if, coincidentally, the internal closing process is defective, or if the presence of the abscess around the vessel leads to such an interference with the nutrition of its walls as to cause ulceration.

If, however, the patient survives, the cavity of the abscess becomes studded with granulations, and gradually heals, as in ordinary cases.

II. When a thread is applied to an artery with sufficient firmness merely to stop pulsation, the internal and middle coats are not divided primarily. A clot forms at the point, and becomes adherent to the internal coat. The *vasa vasorum* at the constricted point being obliterated, the ligature slowly ulcerates through. Should the clot be imperfect, hemorrhage will occur, since the adhesion of the internal coats is much more apt to be deficient than when the ligature is applied tightly. If the thread is drawn tightly enough merely to diminish the calibre of the artery one-half or two-thirds, the artery may remain pervious, or a clot may form, and, becoming adherent to the walls of the vessel, undergo organization. The ligature then ulcerates through the walls of the vessel and the clot, and is cast off.

These methods of tying arteries are particularly objectionable, since almost the whole burden of occluding the vessel is thrown on the coagulum. Should the ligature ulcerate through the vessel before the clot has become firmly adherent, hemorrhage is the inevitable result.

The truth of this inference has been demonstrated on animals, and *a fortiori* must, therefore, apply to man; since, as is well known, secondary hemorrhage after experiment on animals, with the simplest precaution, very rarely or never occurs.

Porta performed seventy experiments to determine the value of the loose or slack ligature. In one-half of the cases the artery was closed by the formation of a clot, the exudation of lymph, or slow contraction from thickening of the external coat. In most of the remaining experiments the artery remained pervious, with little or no alteration in its coats. In a few instances the walls be-

came ulcerated or eroded, and fatal hemorrhage occurred.‡

B. *Changes which occur after the Ligation of an Artery at its Extremity.*

When a ligature is applied to the extremity of an arterial tube (as in cases of amputation), the same processes occur on the cardiac side of the ligature as when an artery is tied in its continuity. The external capsule of lymph does not envelop the ligature so completely. That portion of the vessel within and beyond the noose of the ligature perishes, and is extruded from the wound either in the form of a slough or a purulent discharge.

FIRST CLASS OF LIGATURES: THREADS.

Threads of various composition have been employed in tying arteries ever since ligatures were introduced. Flax, hemp, and cotton were formerly employed; but silk has taken their place in modern times, though the surgeon does not hesitate to resort to the former materials when the latter is not at hand. All of these substances exert the same influence on the animal tissues.

Thus, Porta made *sixty* experiments on the arteries of various lower animals with linen and hempen ligatures. In only *four* cases were abscesses produced. At the end of two years the ligatures had been absorbed in *ten* cases, while in most of the remaining, changes had occurred indicating the progress of absorption. The action of silk ligatures was very similar to that of other threads, as will be more fully explained shortly.§

A great variety of plans have been pursued in applying threads to arteries.

Paré used a strong double ligature, and did not scruple to include "some portion of the neighboring parts," as the vein and nerve.

Hunter in his first operation for aneurism, in 1785, tied the femoral artery with four separate ligatures drawn tight enough to bring the sides of the vessel in contact, and left the ends hanging from the wound, which he closed with adhesive plaster. After the occurrence of secondary hemorrhage, which was checked by the tourniquet, the wound healed, but abscesses continued to form, and pieces of ligature to be discharged, for six months afterwards. In his second case he tied both artery and vein with a single strong ligature, and dressed the wound from the bottom; the man died of secondary hemorrhage. After this he tied the artery alone with a single strong thread, and endeavored to heal the wound as rapidly as possible.

The subject of temporary ligatures is not devoid of interest. Some experiments by Mr. Jones led him to infer that an artery will become obliterated if its internal coats are divided in several places by the momentary application of ligatures. Mr. A. C. Hutchinson found the same result ensue when only a single division of the coats was made; but this was not confirmed by Hodgson and Dalrymple, who repeated his experiments. It occurred

‡ British and Foreign Medical Review, July, 1846, p. 97.
§ *Op. cit.*, p. 92.

to Mr. Travers that the cause of these failures was from the divided coats not being kept long enough in contact to insure adhesion. To test this theory he made eleven experiments on the carotids of horses and asses, leaving the ligature *in situ* from one to twenty-four hours, and in nearly every instance succeeded in obtaining obliteration of the artery by "albuminous or sanguinous coagulum." Long afterwards, Porta repeated Mr. Hutchinson's experiments, but with a different result: out of seventy-four cases in which the ligature was left *in situ* from one minute to twelve hours, he obtained obstruction of the vessel in only *fourteen* instances.

In 1817, Travers put his plan into practice in treating some cases of aneurism. In one case, the brachial was constricted for fifty hours with perfect success. In another instance, a ligature was left on the femoral twenty-seven hours, but pulsation recurred, and the ordinary operation was resorted to with success. In a third case, the attempt to use the temporary ligature resulted disastrously: Mr. Travers applied a ligature to the femoral for aneurism of the posterior tibial, and attempted to remove it on the third day, but found it impossible. Hemorrhage occurred, and on the fifth day another ligature was applied. Death ensued in a few days from a recurrence of the hemorrhage.*

Sir Astley Cooper, in a case of popliteal aneurism, applied a ligature to the femoral, and withdrew it in thirty-two hours; pulsation recurring, the thread was re-applied for forty hours. Hemorrhage now ensued to such an extent that it was necessary to employ the ordinary ligature. In a similar case in which Hutchinson applied two ligatures one-fourth inch apart, and withdrew them in six hours, pulsation returned; two more ligatures were applied; hemorrhage followed, amputation was performed, and the man died.

Considering the discouraging results obtained by the use of the temporary ligature, an attempt to revive it would scarcely be deemed wise. Yet such an attempt was made by Drs. Peters, Buck, and others, of New York, in 1868, but without success.

Scarpa† employed in cases of aneurism a species of temporary ligature which has been termed the *mediate ligature*. He used a cord composed of five or six threads, and placed a piece of linen between it and the vessel; the whole was removed in three or four days. This formidable procedure led to profuse suppuration, and other bad results, and it is not likely to be resuscitated.

Porta made eighty-five experiments with the *mediate ligature*. In twenty-four of these the artery was found pervious; in forty-five, closed either by plug (thirty-four cases) or lymph (eleven cases); and in sixteen, divided in two. Consequently it may be seen that with this method it is not even certain that the vessel will become obliterated.

The method pursued by Tenon, Abernethy, and others for the cure of aneurism, which consists in tying the artery in two places and dividing it between them, has nothing to recommend it. Accord-

ing to Porta, it is a dangerous method. In forty-five experiments to determine its value, hemorrhage from corrosion of the cardiac extremity occurred in three,—a result which was never seen after the common ligature.‡

The ligature of reserve, which consists of a loose thread placed above one applied in the ordinary manner, was much in vogue with English surgeons during the first quarter of the present century. This method necessitated the stripping of the vessel from its connections to a dangerous extent, and thus invited the very accident which it was designed to avoid,—secondary hemorrhage.

The plan of cutting both ends of the ligature short and burying it in the wound will be considered in the next section.

Veitch, of Edinburgh, in 1803, was the first to employ the modern method of applying the ligature, which consists in tying the vessel firmly with a single silk thread of moderate thickness, cutting one end close to the knot, and leaving the other hanging from the wound.

SILK LIGATURES.

Although silk, strictly speaking, is an animal substance, yet its action on the tissues is exactly similar to that of threads of other materials, and it has therefore been placed among thread ligatures, of which it may be taken as the type.

Experiments on Animals.

Where it is not otherwise stated in the following experiments, the ligatures were drawn firmly so as to divide the internal coats, the ends cut short, and the wounds closed by adhesive plaster or sutures.

Levert, of Alabama, in 1828, made some experiments with silk in order to compare its effects with those of metallic ligatures. They are not important; but, as the paper which contains the account has attracted much attention, they will be briefly given:

1. The humeral artery of a dog was surrounded with a single strand of waxed silk, drawn barely tight enough to bring the sides of the vessel in contact. On the fourteenth day a dissection of the parts was made, and the ligature found loose in the centre of a small abscess. The vessel had been ulcerated through, and its ends were separated a short distance.

2. The femoral of a dog was tied in the same manner. On the seventeenth day the ligature was found loose in a small abscess.§

Simpson briefly stated that he has repeated Levert's experiments and obtained identical results. He also states that in numerous instances in which he has inserted pieces of silk in the muscles of the lower animals suppuration has always ensued.||

Porta, in his elaborate work, gives the details of numerous experiments on the arteries of dogs, sheep, goats, calves, horses, asses, and rabbits. In nineteen out of one hundred and twenty experiments, the ligatures had disappeared by absorption at the end of two years. Most of those remaining had undergone changes indicating the progress of absorption. Some

§ Amer. Jour. Med. Sci., vol. iv., 1829, p. 17.

|| Simpson on Acupressure, Appendix.

became encysted *in situ* around the remains of the arteries; some were lying bare in the layers of cellular tissue; and a few had caused suppuration and been thrown off. Compared with catgut, silk produced more irritation and excited suppuration more frequently. Compared with linen and hempen threads, no difference was discovered in the results produced.

Lister, in 1869, made the following experiment:

The carotid of a horse was tied with a piece of purse silk which had been saturated in a strong watery solution of carbolic acid. The wound, which was dressed antiseptically, healed by first intention. On dissection, six weeks afterwards, the ligature was found encysted at the point of application; it had not cut through the vessel.*

There is nothing peculiar in the results of this experiment, as will be seen by a glance at those of Porta.

Howard tied the carotid of a sheep with silk, diminishing the calibre of the vessel one-half. He stitched the free end of the ligature to the integument. In twenty-three days he found the entire ligature hanging to the integument. The artery was obliterated, though no signs existed that it had been divided. It was surrounded by a mass of lymph; no pus was present.†

Experiments of the Writer.

Exp. I.—A coil composed of eighteen inches of saddler's silk was placed in the abdominal cavity of a cat, and the wound closed by silk sutures. The orifice healed by first intention. In twenty days the animal was killed, and the parts examined. The sutures were in place. The coil of silk was found in a capsule formed by the adhesion of the omentum to the abdominal walls. No pus existed.

Exp. II.—The flexor muscles of the thigh of a cat were surrounded subcutaneously with saddler's silk. No disturbance ensued. On examination, twenty days after, the silk was *in situ*, having caused no apparent change in the contiguous tissues.

Exp. III.—A piece of silk, one foot long, was placed beneath the integument of the shoulder of a cat, and the incision closed with silk sutures; it healed by adhesion. Six days afterwards the silk was found *in situ*, surrounded by a thin film of organized lymph.

Exp. IV.—The above experiment was repeated, with identical results.

Exp. V.—The abdominal aorta of a cat was tied with saddler's silk, and the inguinal wound closed by silk sutures. Union by adhesion occurred, but a large fluctuating tumor formed in the groin. In five days the animal was killed. The ligature was found *in situ*, and the parts around it healed. The pelvic cavity contained a large circumscribed abscess, the result of the dissection necessary in reaching the aorta.

Exp. VI.—The brachial of a goat was tied with sewing-silk. Silk sutures were used. Wound healed by adhesion. In fourteen days the ligature was found in place around artery, surrounded by organized lymph.

Exp. VII.—The carotid of a goat was tied with a single thread of saddler's silk, and three-fourths of an inch farther up with a threefold cord of the same material; sutures of silk were used; the wound healed by adhesion. In thirty-two days the animal, which had been sickly, died. Both ligatures were found encapsulated; the smaller surrounded the remains of the artery, the larger had nearly divided it. No pus was present. This experiment is an imitation of one by Lister with carbolized catgut, which will be detailed hereafter.

Exp. VIII.—The carotid of a cat was tied at one

point with silk, and at another, one-half inch above, with catgut (non-carbolized). The wound was drawn together by fine silk sutures; it healed by first intention. In sixteen days the parts were examined; the silk was encapsulated, and had nearly divided the vessel; the catgut was also encapsulated; it was very much softened, and partly absorbed. The artery presented no appearance to indicate that it was undergoing division at this point.

Exp. IX.—The carotid of a large dog was tied at one point with lead wire (drawn firmly), and one inch above, with silk. The wound was drawn together with silken suture; but it was slow in healing, on account of the constant efforts which the animal made to irritate it. On examination, in forty-two days, the artery was found obliterated between the points of ligation. No traces of either ligature could be found.

RESULTS OF THE USE OF SILK LIGATURES ON MAN.

1. *The Short Silk Ligatures.*—A remarkable series of observations on this subject was commenced about 1786, and terminated (by Mr. Lister) in 1869. I refer to the method of tying arteries firmly with silk thread, cutting the ends short, and endeavoring to heal the wound by first intention.

The results of the first cases in which this was tried are given in a letter written by Mr. Haire, of England, in 1786:

"By following this plan we have seen stumps healed in the course of ten days. The short ligature thus left in commonly made its way out by a small opening in a short time, without any trouble or the patient being sensible of pain."‡

Hennen, in 1813, tried the short ligature in many cases of amputation. Some of the ligatures came away with the dressings, some made their appearance in small pustules which formed on the surface of the stump, and a few never came to the surface.§

In 1814 Lawrence published his experience. He used a very fine variety of silk, and found that the ligatures came away with the discharges; or when the wound healed by first intention they came away with trifling suppuration, or occasionally remained. He applied the short ligature to the treatment of aneurisms, but after prolonged experience came to the conclusion that it generally caused suppuration, and abandoned it altogether.

Guthrie, and other eminent surgeons, after similar experience, came to the same conclusion.

Occasionally, after a ligature was left in the tissues the wound healed, and it was extruded in a very curious manner, without suppuration, as in the following case:

The brachial artery was tied for aneurism. The wound healed in thirty-nine days. On the sixty-second day a small tubercle which had been felt in the centre of the cicatrix for some time made its appearance above the skin. It was found to contain the ligature. No suppuration or discharge of any kind occurred.||

Sometimes the ligature remained permanently encysted, as in the following case:

* Lancet, April 3, 1869, p. 451.

† Trans. Amer. Med. Assoc., 1872.

‡ London Med. Jour., vol. vii.

§ Military Surgery, p. 75.

|| Cooper's Surg. Dict., art. "Ligature."

The external iliac was tied for popliteal aneurism. The man died in five months, and on dissection the ligature was found lying close to the artery in a small cyst, something like an inguinal gland.*

Lizars gives an instance where the subclavian was tied for axillary aneurism, with flax thread cut short. The wound healed completely by the third day, and nothing was ever seen of the ligature.†

Carwardine tied the femoral for popliteal aneurism with a short ligature of fine silk. The wound united by first intention, without the formation of a drop of pus, and nothing was ever seen of the ligature.‡

Porta considers that in rare cases a silk ligature is absorbed, as not infrequently happens in animals.

Lister, in 1869, published the following case. The left external iliac was tied for aneurism of the femoral, in a lady aged 51. Silk thread which had been soaked in carbolic acid was used, and the ends of the ligature cut short. Under antiseptic treatment, the wound healed completely in four days. The patient died in ten months of aneurism of the aorta. On dissection, a small capsule was found attached to the fibrous remains of the ligated artery. It contained the knot of the ligature, some disintegrated fibres of its noose (showing that partial absorption had occurred), together with a minute quantity of semi-fluid pus.§

To conclude: When a silk ligature is buried in the tissues, and the wound heals over it, it is either Extruded with suppuration;
Extruded without suppuration; or, in some cases, Encysted.

2. *Silk Ligatures in the Abdominal Cavity.*—It might be supposed that silk would not be tolerated in contact with so sensitive a membrane as the peritoneum, but that its presence would inevitably lead to suppuration. Experience, however, has proved the contrary to be the case.

Peaslee, who has obtained at least average good results in ovariectomy, has long been in the habit of ligating the pedicle and all bleeding vessels with silk ligatures, and closing the incision over them. Except in very rare cases, in which he has seen abscesses form and the ligatures come away, he has found this method perfectly safe. In one case he applied fifteen ligatures to bleeding vessels, and no disturbance ensued.||

Keith, of Edinburgh, has also used silk ligatures in similar cases. In one instance he applied thirty short silk ligatures, and the patient made a good recovery, the ligatures never making their appearance.¶

In one case in which the pedicle of an ovarian tumor was tied with silk, death took place on the seventeenth day from exhaustion. On examination, evidence of very slight peritonitis existed. "The pedicle of the tumor was atrophied, but no slough had occurred. The ligature around the largest portion of the stump had nearly slipped off. The other was still *in situ*, and covered by an exudation already somewhat organized."***

From this autopsy we may infer that the ligatures in these cases became encysted.

3. *Results when the Silk Ligature is applied after the Modern Method.*—When an artery is tied in its continuity, the wound frequently heals by first intention, leaving a small orifice for the transmission of the thread, through which a few drops of pus are discharged.†† After a variable period the ligature comes away, and, the artery having become consolidated by the processes already described, all risk of hemorrhage is obviated.

Although statistics cannot be cited on this point, yet it may be received as the result of practical experience, that the presence of the thread does not interfere materially with the healing of the wound, and, consequently, that the use of silk ligatures is not productive of pyæmia.

As secondary hemorrhage has been asserted to occur more frequently after the use of silk than after the use of animal ligatures, it behooves us to inquire into the frequency of this accident, in order that in the proper place the truth of such assertion may be examined into.

The following statistics, although they are the best that can be obtained, afford scarcely a fair view of the subject, for in many of the cases the method of Scarpa and other dangerous procedures were employed, and indeed it is believed that in comparatively few instances has the modern rule of disturbing the connections of the vessel as slightly as possible been followed. Moreover, scattered here and there among the cases are instances in which other besides silk ligatures have been used.

Table of Ligation of Arteries in their Continuity.

Total number of cases.	Vessels tied.	Number of cases of secondary hemorrhage.	Number of cases dying of secondary hemorrhage.	No. dying from all causes.
a 600	All the arteries.	75, or 12½ per cent.	30, or 5 per cent.	168
b 69	Subclavian.	14, or 20 per cent.	9, or 13 per cent.	33
c 167	Carotid.	21, or 12½ per cent.	14, or 8½ per cent.	56
d 118	External iliac.	14, or 12 per cent.	6, or 5 per cent.	33
e 204	Femoral.	22, or 11 per cent.	6, or 3 per cent.	50
f 31	Primitive iliac.	5, or 16 per cent.	5, or 16 per cent.	24

c Norris, *ibid.*

d Norris, *ibid.*, Jan. 1847.

e Norris, *ibid.*, Oct. 1849.

f S. Smith, *ibid.*, July, 1860. Crampton's case, in which catgut was used, has been omitted, as it will be included in another table.

Death is said to have occurred from pyæmia in seven of the above cases: six of Porta's cases (tabes purulenta), and one of Norris's cases of ligation of the carotid (purulent absorption).

In amputations, secondary hemorrhage is of very rare occurrence. Out of three hundred cases (in most of which the silk ligature was used) death was caused by this accident in only five cases (1.66 per cent).‡‡

series of three hundred cases, says, "Secondary hemorrhage is hardly ever a cause of death, except in persons with diseased arteries."*

Pyæmia, on the other hand, is a very common cause of death. Thus, of Bryant's three hundred cases, thirty, or ten per cent., perished of this disease. But there is no reason to suppose that the material of the ligature had anything to do with this mortality.

(To be continued.)

THREE RARE SURGICAL CASES.

BY CHARLES B. NANCREDE, M.D.,

Assistant-Surgeon to the Protestant Episcopal Hospital.

CASE I. *A Rupture of the Biceps Flexor Cubiti.*—

An elderly man, about 60 years of age, came to me at the Protestant Episcopal Hospital during the summer of 1871, complaining of an injury to his arm and shoulder, caused by a fall from his cart. On examining him, I found a singular condition of the biceps of one arm, as if part of its belly were gone, which the man himself had noticed, saying that after the fall his "muscle had gone up his arm." As the accident had occurred some days before, there seemed nothing to be done, especially as he suffered no inconvenience beyond weakness. I concluded at the time that, from making a violent muscular effort to save himself, one head, probably the long one, had been ruptured.

In placing this case on record, I must apologize for the imperfection of the notes; but, as Dr. S. Ashhurst has shown, in the *Philadelphia Medical Times* for January 11, 1873, how rare such accidents are, I thought it worth reporting, even from memory. Dr. Ashhurst, in the above-mentioned paper, states that only one other case besides his own has been put on record, viz., one by Mr. South,† which he also relates from memory.

Case II. *Fracture of a Rib by Muscular Violence.*—

Thomas —, an Englishman, aged 44 years, a gardener by occupation, came to me at the Protestant Episcopal Hospital during the summer of 1873, saying that he had "strained himself" about ten days before, while trying to straighten a scythe-blade, which he held down with one hand, while, seizing the end with a monkey-wrench, he pulled upwards with the other. At first this had not given him much trouble, but the pain had increased until it demanded attention. He was a singularly healthy, vigorous man, never having had any other fracture, and of perfectly regular habits. Much to my surprise, on examining him, I readily detected bony crepitus, etc., at about two and a half inches from the sternum, on the second rib. The crepitus was so marked that without any difficulty two or three other gentlemen, who were present, confirmed the diagnosis. He was treated by adhesive straps, etc., and did well.

This case has proved unique so far as I have been able to ascertain by reading or inquiry. Malgaigne has collected eight cases due to muscular violence, but thinks that in all of them there was atrophic thinning. They were reported by Gooch, Monteggia, Graves, C. Broussais, Nankivel, and one occurred at the Hôpital Necker. Four occurred in men, and four in women. The age is given in six: five were in persons between forty-seven and sixty-

three years of age, the sixth being a young man. He says that in seven cases the cause was a severe effort at coughing. In M. Broussais' case the patient had chronic pneumonia and eccentric hypertrophy of the heart, to which latter M. Malgaigne is inclined to attribute some influence, as the fracture occupied the fourth true rib at the junction of its anterior fourth with the rest of the bone. In all these cases the seat of lesion was in the anterior half, near the cartilages. He also says, "What is not less remarkable is that so far no instance has been known of such a fracture occurring on the right side. In the cases hitherto known, the ribs involved have been the fourth, fifth, and sixth, then the ninth, tenth, and eleventh, the seventh and eighth being exempt. Generally but one rib is affected; once only the fracture occurred simultaneously in the fifth and sixth; and in the curious case at the Hôpital Necker there took place in less than one month three successive fractures, affecting first the tenth, then the ninth, and lastly the eleventh rib. On the whole, the tenth seems to be the rib most exposed."‡ Now, in my case, the fracture was that of the *second* rib of the *right* side.

Malgaigne thinks these cases were due to muscular action, which in coughing produces the fracture by approximating the sternum and spinal column, just as external pressure does. Whether this is the explanation of the mechanism in my case I am not prepared to say, although the effort, as the patient described it, *would* tend slightly to approximate the anterior and posterior walls of the chest on one side—the side of tension,—and *expand* it on the other side,—that of prehension.

It might be urged that this was a fracture of an ossified cartilage; but I think not, although it was very near the junction; besides, the patient's age is against this, he being only forty-four years old, with no signs of premature decay—indeed, the reverse. The crepitus was such as could only have been produced by a cartilage as calcareous as bone itself.

Case III. *A Luxation of the Lower End of the Ulna forwards.*—

Eliza Wade, aged 17 years, a mill-girl, came to the Protestant Episcopal Hospital in March, 1874, having had her right wrist injured by her hand being caught between the spokes of the fly-wheel of a spooling-machine, which made a complete revolution before she could stop it. On examination, I found the hand bent back, pronated, and directed towards the radial side, the fingers semi-flexed, and the styloid process of the ulna projecting at the front of the wrist. After etherization, I readily reduced the luxation by seizing the fore-arm with one hand, while with the other I made extension, at the same time pressing the carpal bones downwards. There was no tendency to displacement. All the carpal bones seemed loosened, as it were, and the cartilage must have been torn off at the inferior radio-ulnar articulation, as there was crepitus there. Nothing, however, like a fracture in the sense of an appreciable fragment of bone could be detected.

This was readily determined, as I examined the case within half an hour after it occurred, and before swelling had supervened.

Malgaigne has collected nine cases of this luxa-

‡ Malgaigne's Treatise on Fractures, p. 348.

tion, and Hamilton one, reported by Parker, of Liverpool. These, so far as I am aware, are all that have been put on record up to the present time.

In most cases the reduction is readily effected "by pushing the ulna towards its socket, while an attempt is made to flex the hand, or by extension, supination, etc.," according to Hamilton; but Parker could only effect this while the hand was pronated. I give his own words: "Several ineffectual and very painful attempts were made to accomplish the reduction, by pushing the head of the ulna into its natural position. This was at last effected by seizing the hand to make extension (counter-extension being made at the elbow), then forcibly pronating the hand, at the same time pressing backwards the dislocated head of the bone with the fingers of the left hand. After persisting for a short time, the bone was felt to assume its natural position."* My case was also reduced while the hand was pronated.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

SURGICAL CLINIC OF PROF. S. D. GROSS, M.D.

Reported by T. H. FENTON.

PROTRUSION OF SCAPULA.

IDA D., aged 13 years. You notice in this case, gentlemen, two distinct prominences on the back in the region of the scapula. The affection is nothing very remarkable, being simply a projection of the inferior angle of the scapula farther backwards than is customary. The difficulty is owing simply to a relaxed condition of the parts, especially the latissimus dorsi and great serrated muscles. The latissimus dorsi, as you all well know, arises from the spinous processes of the sacrum, the lumbar vertebrae, and the seven lower dorsal vertebrae, and also from a portion of the spine of the ilium. The fibres of the muscle pass upwards and outwards, over the inferior angle of the scapula, to the axilla, where they become twisted, and are finally inserted into the inner edge of the bicipital groove. The deformity is very unseemly. It happens mostly in girls, especially factory-hands who are the day long working in rooms filled with confined and vitiated air; it is also seen in children of a strumous disposition, and in school-girls. The accident is very rare in boys. Sometimes, owing to great violence, the scapula may be detached from its muscular connections, but this is very rare indeed. A remarkable case came under my notice, happening to a boy who was detected kindling a fire in the cellar of a stable. The owner of the property in his anger took the boy and threw him up on the sidewalk. A consultation was called, and the physicians, both of whom were young, stated that a dislocation of the scapulæ from their muscular attachments had taken place as a result of the violence. Suit for damages was brought against the man. I was called in as an expert, and, after examining the child, I testified that the difficulty was not owing to the violence, but due to the relaxation of the parts. Notwithstanding all my experience and years, a verdict of eight hundred dollars was rendered against the defendant, which was unjust in every sense. In the case of the child before us, I shall order a brace to be worn with the

pressure applied directly over the inferior angle of each scapula. She will be put upon the use of iron and quinine, and have the cold shower-bath applied daily. We will also slap the parts twice in the twenty-four hours with the ends of a fringed towel dipped in cold water; this promotes the nervous action. You may, if you please, also use the veratria ointment; the patient must always sit on a chair or bench with a back, and not be allowed to bend forwards.

TRANSLATIONS.

CÆSARIAN SECTION.—Dr. Fritz Schurig gives an account of this operation, as performed by him on a patient 37 years of age, in whose case safe delivery was impossible by reason of a condition of osteomalacia. The procedure was as follows. An incision, six inches in length, was made in the line of the linea alba, when the uterus presented itself in a condition of complete anteversion, with the ovarian ligament and the broad ligament protruding through the wound. Afterwards the uterus was turned, and, being pressed against the abdominal walls by an assistant, was also opened by an incision. The placenta proved to be attached anteriorly, and after its removal the living child was seen lying with its buttocks forward, and with the head somewhat turned to the left, owing to its unfavorable position for several days previously. The uterine wound bled freely. The abdominal wound was closed by ten sutures, aided by strips of adhesive plaster. Shortly after the operation the patient succumbed, owing to loss of blood.

The post-mortem examination showed the bones highly hyperæmic, the form of the pelvis indicative of osteomalacia, and the last lumbar vertebra strongly pressed downwards, as after spondylitis. The various bones of the pelvis were movable at their junctures. Four months previous to delivery, the patient experienced a sensation as if something in the pelvis had become *sprung*, or as if the pubic bones had become partly separated. This latter fact is of interest in connection with the proposal to divide the symphysis pubis in narrow pelves.—*Jahrsb. d. Gesells. f. Nat. u. Heilkunde.* A. V. H.

TRANSFUSION IN THE TREATMENT OF CHOLERA (*Inaug. Dissert.*, Berlin, 1873).—G. Kalisher reports two cases of cholera, treated by transfusion of blood, in Berlin, during the last epidemic of this disease. In both cases the blood was injected into the basilic vein; the operation in one case being followed by recovery, and in the other by death. He reports also another case, treated in the same manner, in which the operation was followed by recovery. Among fourteen cases which he found reported in the journals, there was but one recovery. After the operation, however, there was usually noticed some amelioration of the condition of the patient, the pulse became stronger, and the occurrence of death seemed to have been retarded. A. Netter (*Gazette des Hôpitaux*) states that Lorain, after injections of water into the veins, always noticed an improvement in the general condition of the patients, and in one case in which life had been despaired of, recovery took place. The amount of water injected in this case was but 400 grammes, but the patient drank large quantities of the same fluid while under treatment. Netter agrees with Goltz in thinking that the injection of water into the veins is as satisfactory as that of blood or saline solutions, and concludes that the only use of transfusion is the introduction of fluid, by which the circulation is again rendered possible. W. A.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 23, 1874.

EDITORIAL.

INCREMENT OF POPULATION.

ACCORDING to a recent English journal, the following table represents accurately the increase in the commerce and population of the Christian world during the last seventeen years. It is of great interest on account of its bearing upon the questions whether the population multiplies too fast for the good of the race, and whether the general comfort of the individual is being increased or decreased :

	FOREIGN COMMERCE.		POPULATION.	
	1855.	1872.	1855.	1872.
Great Britain.....	£268,400,000	£609,600,000	27,620,000	32,000,000
France.....	150,300,000	285,800,000	35,750,000	36,100,000
United States.....	107,340,000	232,800,000	27,000,000	41,000,000
Belgium.....	69,000,000	199,800,000	4,530,000	5,100,000
Germany, imp'ts only	53,200,000	100,000,000	33,500,000	39,400,000
Austria.....	26,000,000	89,400,000	36,500,000	35,900,000
Russia in Europe.....	45,400,000	103,000,000	65,000,000	71,000,000
Italy.....	32,200,000	103,600,000	18,850,000	27,000,000
Spain.....	32,500,000	27,800,000	15,600,000	16,370,000
Netherlands.....	54,000,000	88,000,000	3,433,000	3,650,000
Sweden.....	9,000,000	14,600,000	3,660,000	4,100,000
Total.....	£848,340,000	£1,855,200,000	271,443,000	311,620,000
Increase in 17 years (commerce).....			118.5 per cent.	
Increase in 17 years (population).....			14.8 per cent.	
Foreign commerce in 1855 per head of population.....			£3.13	
Foreign commerce in 1872 per head of population.....			£5.95	
Increase per cent.....			90	

The most striking deduction to be made from this table is not the great increase of commerce, but the fact that in seventeen years the amount for each individual has nearly doubled. There has been a slow growth in the number of the people, but a very rapid growth in the commerce. Commerce is an index of wealth, and increase of wealth means, in the highest degree, augmentation of physical comforts and well-being. Evidently there is no present danger of the race becoming extinct by an increase

of the population beyond the power of production, but there is a steady augmentation of the material things of life, so that every man has more to offer to his neighbor in exchange,—the surplus of the necessities of life in the one clime being the luxuries of another.

PROCEEDINGS OF SOCIETIES.

PENNSYLVANIA STATE MEDICAL SOCIETY.

THE Medical Society of the State of Pennsylvania met at Easton, Wednesday, May 13, at 3 P.M., to hold its twenty-fifth annual session, in the chapel of the Reformed Church.

The meeting was called to order by the President, Dr. S. B. Kieffer, of Carlisle, when the Society was led in prayer by Rev. W. C. Cattell, D.D., President of Lafayette College.

The Chairman of the Committee of Arrangements, Dr. Traill Green, welcomed the delegates to Easton, in a very appropriate speech.

Dr. Green then reported the programme for the meeting, which was adopted, after which the roll was called by the Secretary, the members present numbering in all 129.

Dr. Stetler, of Philadelphia, then made a motion that the regular order of business be suspended to enable the President to deliver his Annual Address at Pardee Hall that evening. He also moved that the regular order be suspended to consider the following amendment to the Constitution, proposed during the session last year by Dr. Atlee of Lancaster; which was adopted.

The section reads thus :
"Any member of a County Society who is censured, suspended, or expelled shall have a right to appeal to the censors of the district, provided the said appeal shall be filed within three months after the date of said act of censure, suspension, or expulsion. The decision of the censors shall be final. Three censors shall constitute a quorum."

The amendment is to strike out the word "final" in the above section, inserting "reported to the State Medical Society at its next meeting for final action."

The matter was discussed by Drs. J. L. Atlee, H. Corson, and others, and adopted by a vote of two-thirds.

On motion of Dr. Green, Dr. P. D. Keyser, of Philadelphia, then read an abstract from his paper on Operation for Cataract, as follows :

Report on One Hundred and Thirty-two Cataract Extractions.

During the past six years, 1868 to 1873 inclusive, I have made 132 extractions of cataract, of which number 60 were made in the Philadelphia Eye and Ear Infirmary, 23 in the Wills Ophthalmic Hospital, and 49 in private practice.

Of the operations performed, 120 were made according to Von Graefe's modified linear method, 3 were made according to Daniel's corneal flap method, 3 were made according to Pagenstecher's method, 3 were made according to Liebreich's method, and 3 were made according to Bowman's suction method.

The ages of the patients ranged from 17 to 82 years.

The acuity of the vision obtained was, in 1 case, $\frac{15}{XX} = \frac{3}{4}$; in 9 cases, $\frac{20}{XXX} = \frac{3}{8}$; in 11 cases, $\frac{20}{XL} = \frac{1}{2}$; in 18 cases, $\frac{20}{L} = \frac{2}{5}$; in 15 cases, $\frac{20}{LXX} = \frac{7}{10}$; in 41 cases, $\frac{20}{C} = \frac{1}{5}$; in 1 case, $\frac{15}{C} = \frac{5}{20}$; in 1 case, $\frac{10}{LXX} = \frac{1}{4}$; in 17 cases,

$\frac{20}{CC} = \frac{1}{10}$; in 3 cases, $\frac{15}{CC} = \frac{3}{40}$; in 1 case, $\frac{5}{LXX} = \frac{1}{14}$; in 5 cases, $\frac{10}{CC} = \frac{1}{20}$, and in 5 cases, closure of the pupil, which can be operated on, and 4 cases total loss.

Classified according to success of operation with vision, we have—Vision to $\frac{1}{10}$ as perfect, 114 cases, = 86 $\frac{4}{11}$ per cent.; $\frac{1}{10}$ to $\frac{1}{20}$ as moderate, 9 cases, = 6 $\frac{1}{11}$ per cent.

Good success, total 93 $\frac{2}{11}$ per cent.

Imperfect, some of which may be improved by operation, 5, = 3 $\frac{3}{11}$ per cent.

Complete loss, 4, = 3 $\frac{1}{11}$ per cent.

In four of the cases iridectomy was made 6 to 12 weeks previous to the extraction of the lens.

Hemorrhage into the anterior chamber occurred in 25 cases. In 19 cases the lens was removed by a traction instrument. Escape of vitreous occurred 9 times.

Iritis, with closure of the pupil, took place in 9 cases; in two of which iridectomy was made afterwards with perfect success, and iridotomy also twice, with good results.

The instrument used for the iridotomy operation was a modification of De Necker's scissors, made by Messrs. Gemrig & Son, of Philadelphia. In both cases a large triangular piece of the iris was easily and readily removed, by which means a good-sized pupil was obtained.

Secondary cataract formed in four cases, which were afterwards operated on with good success.

Severe intraocular hemorrhage took place in one case after the extraction of the lens.

Sloughing of the cornea occurred once only.

Irido-choroiditis, with phthisis bulbi, one case.

In one case death took place from acute abscess in the brain forty-eight hours after a secondary operation for the removal of a band of lymph across the pupil.

Astigmatism was found in fifty-eight cases after the operation, necessitating the use of cylindrical glasses. The great majority of these came, no doubt, from the operation causing a change in the curvature of the cornea.

In the operations by Von Graefe's method the incisions were made in the sclerotic, beginning at the sclero-corneal junction, and the most of them brought out in the same with a large conjunctival flap, while in others the incision was brought out in the cornea close to its edge. Those brought out in the cornea did not heal so quickly, although quite as well, when there was a conjunctival flap.

In many of the cases, the upper part of the anterior capsule was removed after its rupture, as recommended by Knapp.

In a few cases, where secondary cataract was feared, the posterior capsule was ruptured and torn aside, very little, if any, vitreous was lost, and all healed well with perfect to $\frac{1}{10}$ vision.

Care was taken before closing the eye to remove the edges of the incised iris from the corners of the sclerotic wound into the anterior chamber. In some cases, where the pupil was drawn too much upward by the edges of the iris having healed in the sclero-corneal wound, it was relieved by simply cutting the iris loose from its attachments in the cicatrix, by making an incision in the cornea on the line of the former wound with a lance-shaped iridectomy knife, and introducing the small iridectomy scissors, allowing one branch to pass under and the other over the iris, and snipping it through as close to the cornea as possible.

Atropia being put in the eye before and after the operation, caused the iris to dilate, and, being free, resumed its normal position. This was found a more satisfactory operation than iridectomy; there is less hemorrhage into the anterior chamber, and it gives a better-shaped pupil.

NOTE.—After the report was written and laid before

the Philadelphia County Medical Society for the State Medical Association, case No. 119 was on May 6 re-examined, and it was found that her vision had improved from $\frac{5}{LXX}$ to $\frac{12}{C} = \frac{1\frac{1}{2}}{8}$, and with $+1\frac{1}{8}$ could read Jäg. 5 readily.

By this the percentage of perfect success is increased to 87 $\frac{4}{11}$, instead of, as above, 86 $\frac{4}{11}$.

The paper was referred to the Committee on Publication.

Dr. S. Caro, a representative from the New York State Medical Society, being formally received, then addressed the Society.

After due motion, the order of business for Thursday was arranged, the first addresses being those on Surgery, Obstetrics, and Medicine.

A Committee on Unfinished Business, composed of Drs. Stetler, of Philadelphia, H. Corson, of Conshohocken, and E. A. Wood, of Pittsburgh, was appointed by the President.

On motion, the report of the Committee from last year on the Revision of the Censorial Districts was taken up and read, and adopted after due discussion.

According to this action, the State is divided into thirteen Districts, each of which has a Censorial Board of three members, to which one member from each County Medical Society is eligible.

Other less important amendments, offered at the last meeting of the Society, were read, and adopted without opposition.

On motion of Dr. Green, the Society adjourned to give the County Societies opportunity to select their representatives for the Committee on Nominations.

Wednesday Evening.—The Society assembled in the auditorium of Pardee Hall at 8 o'clock. The Hall was filled with ladies and gentlemen from the College and town. Some of the members of the Society have their wives with them, and they were present also. On the stage sat the former Presidents of the Society, the Vice-Presidents, and Dr. Traill Green, who introduced Dr. S. B. Kieffer, of Carlisle, the President of the Society, who delivered the annual address, which was received with much applause and by motion was referred to the Committee on Publication.

Before adjournment the Committee on Nominations was announced by the Secretary, viz.: Beaver, Dr. Jackson; Berks, Dr. Weidman; Allegheny, Dr. Wood; Blair, Dr. Clark; Bradford, Dr. Conklin; Columbia and Montour, Dr. Pursell; Cumberland, Dr. Mosser; Dauphin, Dr. Orth; Delaware, Dr. Roland; Franklin, Dr. Snively; Huntingdon, Dr. Shade; Indiana, Dr. Rutledge; Lancaster, Dr. Davis; Luzerne, Dr. Murphy; Lycoming, Dr. Crawford; Mercer, Dr. Fulton; Mifflin, Dr. Hersberger; Montgomery, Dr. Corson; Northampton, Dr. Bachman; Perry, Dr. Swartz; Venango, Dr. Richey; Clearfield, Dr. Burchfield; Philadelphia, Dr. Eshelman; Schuylkill, Dr. Halberstadt; Susquehanna, Dr. Ainey; Tioga, Dr. Maine; York, Dr. Bailey.

SECOND DAY.

Thursday Morning.—The early part of the morning was occupied by the members of the Society in inspecting the College buildings, museums, laboratories, and halls, and in the preliminary meetings of committees.

The Society was called to order at half-past nine o'clock, in Pardee Hall, the minutes of the previous meeting being read and approved.

An address, prepared by Dr. Thomas M. Drysdale, of Philadelphia, now travelling in Europe, was first read,—subject, "Surgery,"—Dr. Washington L. Atlee, of Philadelphia, reading the report by request.

Dr. Drysdale chose Tracheotomy, regarding it as equally important to the surgeon and the practitioner, "since it brings back to life one who is suffocating and

is at the point of death." Every practitioner should be ready to perform it. It is required for inflammation of the larynx and trachea, and its results; spasm of the larynx; abnormal growths in the larynx; paralysis of the larynx; pressure from tumors, aneurisms, or abscesses; foreign bodies in the windpipe. He then mentioned, under each head, the diseases or accidents likely to require this operation. He then detailed, somewhat minutely, the anatomy of the parts involved in the operation. The instruments required were a sharp scalpel with a good point, a blunt-pointed bistoury, a director, a tenaculum, a pair of sharp-pointed straight scissors, dissecting-, torsion-, and dressing-forceps, two blunt hooks or curved spatula, a dilator, a canula adapted to the age of the patient, with tape to secure it, a small sponge probang, a gum-elastic bougie of a size which will pass through the canula, a syringe and tube to pass into the trachea to use if the operator fears to apply his mouth to the wound to suck out the blood from this organ; plasters, sponges, water, and towels also at hand.

The dilator should be curved at a right angle: it has three branches of equal length, which are grooved on the inside; and it opens by pressure.

The canula should be the ordinary double canula, with the improved neck-plate of Mr. Rogers, made so that while the neck-plate is fixed the tube is allowed to follow partially the motions of the trachea. An important point is that the canula should be double, that the inner tube may be withdrawn and cleansed without disturbing the outer. The surgeon should have canulae of various sizes, and use the largest.

Anæsthetics should be employed except where the patient is asphyxiated and nearly or quite insensible, or in cases of sudden suffocation.

This operation includes laryngotomy, laryngo-tracheotomy, and tracheotomy. He then described in detail each of these operations. He next considered the difficulties attending the operation. *Hæmorrhage*: Use the knife as little as possible after the first incision, substituting the handle, the director, and the fingers.

Ligate, if practicable; but if time will not suffice, open the trachea at once, introduce the tube, and if any blood has entered apply the mouth and suck it out. Of course this cannot be done where there is contagious disease: here the syringe should be employed; but if it becomes imperative, the operator should not neglect the precaution of Dr. Gross, of "washing out the mouth and throat well, immediately after, with a strong solution of chlorinated soda or some other disinfecting fluid, for the purpose of promptly neutralizing the poison contained in the secretions of the parts."

Hæmorrhage is rarely fatal if the surgeon does not lose his presence of mind. Always complete the operation, however forbidding the aspect of the case. The surgeon may lose the opening, owing to the fact of making it too small, or a convulsive effort may ensue; do not spend much time, but make another. The after-treatment requires care.

The air should be kept moist. Keep lime constantly slaking near the patient, both for its steam and its dissolvent effect. Attend to the tube: withdraw and cleanse it every two hours at first, or oftener if necessary. Pass a bougie, to cleanse if necessary, down into the trachea. This causes cough, and matters are thus expelled. A skilful attendant should be the one to look to these matters:

In croup and diphtheria, chlorate of potassium should be freely exhibited. Dr. D. uses a saturated solution, thirty grains to the ounce, a teaspoonful to a table-spoonful, according to age, every half-hour to every three hours. If the bowels are irritated, add a small quantity of opium, and, as the patient progresses, add tincture of iron.

Relief having been secured, the canula may be removed as soon as it can be done without risk. To determine this, stop the end of the tube with the finger, and see if the patient can breathe through the larynx. If so, cork the tube for twenty-four hours. If all goes well, remove the canula and let the wound heal, keeping it clean and covered with a light dressing. It may, in chronic disease, be necessary to wear the tube for life.

Referred to the Committee on Publication.

The next thing in order was the reading of the Address on Obstetrics, prepared by Dr. William B. Atkinson, of Philadelphia, given in abstract, which gave in detail an accurate account of the progress in Gynecology and Obstetrics during the past year. The doctor said that post-partum hemorrhage, its treatment and prevention by anticipation, had occupied the attention of the profession both at home and abroad. Many and learned discussions on this subject had occupied the time of the Societies and the pages of the medical journals. The general conclusion seemed to be that it was surely controlled by the injection of perchloride or persulphate of iron, which might be used even without dilution, and, in the vast majority of cases, without injury. A few observers, among them Dr. Snow Beck, insisted that these injections were highly prejudicial. The other subjects reported upon by Dr. Atkinson comprised almost everything connected with gynecology and obstetric medicine.

Dr. Atkinson reporting in favor of the use of chloral in puerperal eclampsia, the subject created much discussion. Prof. Gross, of Philadelphia, favored chloral, but insisted that the dose must be at least thirty grains, frequently repeated.

Dr. Atkinson also administered it by the rectum when it could not be employed by the mouth.

Dr. Goodell, of Philadelphia, agreed with both gentlemen.

Dr. Hiram Corson, of Montgomery County, took the floor in favor of what is now the unpopular practice of bleeding in cases of puerperal convulsions, pneumonia, pleurisy, and acute hepatitis.

Dr. Atlee, of Lancaster, said he was an "old fogy" in this respect, and related cases where death would have been the result if the use of the lancet had not been resorted to. He had more faith in bleeding, however unpopular it might be, than in bromide of potassium, opium, or the new compound, chloral.

Prof. Gross, of Philadelphia, took the floor again, and said that he wished it distinctly understood that there is at least one teacher in Philadelphia who recommends and insists on the judicious use of the lancet, and he was glad that Mr. Corson had the courage to get up in this enlightened age to advocate the unpopular method of bleeding. He said that fashion rules us too much, and, instead of exercising our own good, strong, common sense, we put too much confidence in men of reputation, especially across in Europe. The day is coming, and now is, that our own authorities in this country should be consulted, and when good sense and sound experience should be followed, rather than fashion.

Dr. G. D. Bruce, of Pittsburgh, referred to the causes of these attacks, necessarily requiring different remedies.

Dr. W. L. Atlee, of Philadelphia, cited an instance in which the subject was bled nearly to death, and until he feared to pursue further bleeding; yet still the convulsions continued. He then gave an emetic, when up came huge chunks of meat, and the patient was instantly relieved. He favored the use of large doses, three to four drops, of croton oil, repeated to hypercatharsis. The irritation of the alimentary canal was, he believed, a great cause of this affection. Similar

remarks were made by Dr. Stites, of Perry County, Dr. Leasure, of Pittsburgh, and others.

Dr. Kieffer, the President, concluded the discussion by a summing up as to the importance of fine discrimination in diagnosis, after which the Society adjourned.

AFTERNOON SESSION.

The afternoon session was held in the chapel of the Reformed Church, being called to order by the President at 2 P.M.

The Permanent Secretary opened the meeting by reading the report of the Committee on additional accommodations for deaf-mutes in the western portion of the State. They had been successful in obtaining an appropriation from the Legislature, had land donated them, and, altogether, very encouraging prospects. The report was signed by Dr. L. Turnbull, of Philadelphia, Chairman. It was received, and ordered to be entered on the minutes, and the Committee was continued.

A paper was also read by the Secretary, from Dr. L. Turnbull, on the Education of Deaf-Mutes.

The writer took the ground that not enough attention was given in our State to teaching the deaf-mute articulation, there being no special institution for the instructing of private pupils, so that we were necessarily obliged to send such applicants to other cities, in New York, Connecticut, and Massachusetts, to receive the advantages of such instruction. But an important change has taken place, not alone in the United States, but also in Europe, in the education of this most interesting class.

Up to a very few years back, the system of teaching the deaf and dumb was exclusively by signs, also a great improvement on their former sad state. In a letter addressed (1873) to his colleagues by M. Léon Vaisse, late director (principal) of the National Institution for the Deaf and Dumb at Paris, upon the occasion of his exchanging the laborious duties of that position for the well-earned repose and dignity he now enjoys under the title of Honorary Director of the institution,* he observes, "In communicating with the deaf, the manual alphabet has the advantage over writing of a greater degree of convenience, inasmuch as it dispenses with all material aid. The manual alphabet, however, may be advantageously replaced in its turn by the labial alphabet, which is far more useful in the ordinary conditions of life.

"It is these exercises in speech that more than anything else can succeed in familiarizing the born deaf-mute with ordinary language, and it is the insufficient practice in them, in the case of too many pupils, that constitutes the weak point of the French system.

"On the special point of the prominence due to articulation in our instruction, I have not succeeded in making you share my convictions. These convictions, however, are of long standing, and are based upon the experience of my personal practice, and upon observation of the movement which of late years has prevailed in so many French and foreign institutions. It is not a question of reviving the old controversy which divided the founders of the French and German schools.

"The teachers beyond the Rhine have ceased to reject pantomime as the first method of intellectual development of their scholars; while, on the other hand, the Swiss and German institutions are not the only ones in which the practice of speech is made an essential element in the education of the child whom we style deaf-mute.

"Among our Northern and Southern neighbors in Belgium, Holland, Spain, and Italy, as well as in Eng-

land and the United States, considerable prominence is now given to this teaching,—in old institutions which have modified their method by the introduction of this new element, and in more recent establishments which have sprung up, besides certain old ones not disposed to modify the principle of their previous method. In France, thanks to the impulse given by M. Fourcade, of Toulouse, as good results in teaching articulation have been and are now obtained in several of the institutions of the departments as have been reached anywhere.

"But now lip-reading or visible speech is becoming the popular mode, and is another advance in the right direction, so as to fit the deaf-mute, no longer dumb, to communicate with society in general."

Dr. Turnbull's paper was referred to the Committee on Publication.

Reports on Meteorology and Epidemics were presented from the counties of Philadelphia, Fayette, Lancaster, Tioga, Adams, Mercer, Schuylkill, Chester, Bradford, Berks, Lehigh, Luzerne, Lycoming, and others. These were referred, without reading, to the Committee on Publication, who will use their discretion as to what and how much shall be published in the Transactions.

A motion was then made, and agreed upon, that all other County Societies be permitted to send their reports to the Permanent Secretary in two weeks.

Dr. Benjamin Lee, of Philadelphia, in presenting the report from Philadelphia County, offered the following:

"Whereas, The interest which at present exists in the scientific world in the question of the comparative merits of cremation and sepulture is, in the opinion of this Society, based upon a well-founded conviction that the latter mode of disposing of the bodies of the dead has in various ways exercised an injurious effect upon the health of the living, and especially by contaminating the sources of their supply of drinking-water: Therefore,

"Resolved, That the several County Societies be, and are hereby, instructed to embody in their next annual reports to this Society a detailed account of the location of the burying-grounds and cemeteries within their respective limits, as related to the springs, reservoirs, or streams on which the neighboring populations depend for their water-supply; including the direction of the water-shed and pitch of the geological strata, an estimate of the purity of the water usually employed for drinking-purposes, and a statement of the more frequent zymotic diseases, and the extent to which they have prevailed during the present conditions as compared with previous periods."

The following test for the purity of the water is suggested as both delicate and reliable: it is that commonly known as *Nessler's test* for the detection of ammonia.

Dissolve 35 grains of iodide of potassium in 3ij 3vj of distilled water; to this add a cold concentrated solution of mercuric chloride, until the mercuric iodide, at first formed and then dissolved by agitation in the solution, at length produces a very small permanent precipitate; 100 grains of caustic potassa are next dissolved in 3vi 3ij of distilled water. Mix the solutions, and add distilled water to make 3xv 3v. This added to water containing .03 grain of ammonia to a gallon will give a yellow color; a larger amount of ammonia, a brownish-yellow color.

Dr. McIntire, Adjunct Professor of Chemistry in Lafayette College, made some remarks upon this test, and upon the difficulty of testing water under various circumstances. Dr. McIntire said that while Nessler's reaction is a most delicate and accurate test for ammonium salts, still much of the animal nitrogen may combine as nitrites, or be oxidized still more into nitrates, which will not be detected by the reagent.

* American Annals of the Deaf and Dumb, January, 1874, 12, 19, 20.

The permanganate of potassium test will show the presence of organic matter, but does not show whether vegetable or animal. While, therefore, if ammonia is shown the water is not good, we may have water showing no reaction with the Nessler solution and yet not proper for use.

The resolution was adopted, and the test referred to the Committee on Publication.

Dr. Allis, of Philadelphia, read a paper upon the *Diagnosis of Obscure Injuries of the Hip*.

He stated that in the March number of the *Philadelphia Medical Times* he called the attention of the profession to the relation the great sacro-sciatic notch bore to the acetabular cavity. That if a pelvis were placed in the position of one lying on his back, the "notch" in the majority of cases will lie *directly below* the acetabular cavity, and from the conformation of the pelvis it would appear possible, and, indeed, very probable, that a dislocation in its direction might not be followed with any shortening of the limb when it is compared with its fellow, on a line with the axis of the trunk. Now, if the limbs are compared at right angles to the trunk, a discrepancy will at once be produced, for the very reason that the head of the bone lies in a new position, an inch or more directly below its normal bed.

(Drawing of a pelvis exhibited.)

The importance of this anatomical feature would appear—

1. In enabling one to determine positively that his efforts at restoration had been successful.

2. In determining complete intracapsular fractures.

3. In determining severe contusions, or incomplete and impacted fractures.

(1) The limb cannot be regarded as restored until its measurements *in the axis* of the trunk, and at right angles to it, correspond.

(2) In complete fractures the usual signs are ever-sion, shortening, and a doubtful crepitus. If in such a case we compare the limbs at right angles to the trunk, while the weight of the sound limb will be sustained by the neck of the femur, the neck of the other being broken, the limb will sink until the trochanteric end shall become arrested by its ligamentous surroundings and thus produce a shortening similar in many respects to the preceding case. Now, to determine that this is fracture and not dislocation, lift the limb to a level with its fellow, and if a force sufficient to overcome its weight will effect this and if on letting go again it sinks an inch or more, it may be confidently asserted that it is fracture of the neck, for if it were a dislocation it would require the strength of one or more strong men to bring the limbs to the same altitude.

(3) Incomplete impacted fractures. This, Dr. A. said, was a feature of the utmost importance, as this variety of fracture was the only one implicating the joint that was likely to result in bony repair.

Rude manipulation in such cases would endanger the impaction and hazard the chances of recovery; hence he enjoined gentleness, warning against an attempt to obtain crepitus. In such a case, place the patient on a level surface, and with no obliquity of the pelvis; notice the relation the limbs bear to each other; then compare them at right angles, and if they still sustain the same relation it may be confidently assumed—

(a) That the head of the bone is in the acetabular cavity.

(b) That no complete fracture is present.

(c) That the injury is a severe contusion or an impacted incomplete fracture, and the nature of the injury, sex, age, persistence of pain, and degree of helplessness, will point out an intelligent and rational course of treatment.

The paper was referred to the Committee on Publication.

On motion of Dr. Murphy, of Luzerne County, Dr. Davis, of Wilkesbarre, was permitted to read his account of a case of vaginal ovariotomy.

Dr. W. L. Atlee evinced much interest in this case, and congratulated Dr. Davis on his success.

Paper referred to Committee on Publication.

The report of Committee on Nominations was then presented by Dr. W. M. Weidman:

OFFICERS FOR 1874.

President, Dr. Washington L. Atlee, of Philadelphia.
Vice-Presidents, Drs. George D. Bruce, Pittsburgh; Rowan Clarke, Antistown; P. B. Breinig, Bethlehem; Alexander Craig, Lancaster.

Corresponding Secretary, Dr. R. J. Dunglison, Philadelphia.

Permanent Secretary, Dr. W. B. Atkinson, Philadelphia.

Recording Secretary, Dr. R. S. Chrisman, Pottsville.

Treasurer, Dr. Benjamin Lee, Philadelphia.

Place of meeting, Pottsville.

Committee of Arrangements, Drs. A. H. Halberstadt, G. W. Brown, J. T. Carpenter, D. W. Bland, L. M. Thompson, O. M. Robbins.

Time of meeting, second Wednesday of June, 1875, at 3 P.M.

Committee of Publication, Drs. W. B. Atkinson, R. J. Dunglison, B. Lee, T. M. Drysdale, L. J. Deal, A. Fricke, Charles McIntire.

Also Censors and Delegates to American Medical Association, and to neighboring State Medical Societies. Report adopted unanimously.

Dr. J. L. Atlee, of Lancaster, then stated that his brother, Dr. Atlee, President elect, being compelled to absent himself by next train to Philadelphia, desired to return his thanks for the honor conferred on him.

Dr. Washington L. Atlee then briefly addressed the Society as follows:

He thanked the members for this honor, quite unsolicited by him. Office should seek the man. He accepted, knowing his want of familiarity with parliamentary usages. To preside over an assembly of professional men whose sole aim is the progress of science, the amelioration of human suffering, the promotion of public health, and the cultivation of social intercourse, must be inspiring.

Medical art and science, as applicable to man, have originated out of the necessities of the race, and belong to all classes. The cultivation of medicine is a common duty, as it partakes of a common interest.

The temple of science is built by all.

He would impress upon all committees the necessity of faithful attention to their duties. It is hoped that none will accept a position without they intend to fully perform their duties. We should have no sinecures. Let us all work. Then our Society will assume a proud position among her sisters of other States, and our annual Transactions will be a monument to our industry and worth.

By these reunions, while we cultivate the best feelings of the heart, we at the same time, by honest brain-work, will add to mental culture, and contribute largely to the stores of medical knowledge.

In conclusion, he expressed the sentiments of every member in acknowledging the courtesies and attention received from the citizens and the profession of this town, nestled as it is in the bosom and embrace of the most romantic and picturesque valleys of the State. Easton, its people, its schools of learning and science, its manufactories, has left an impression upon each of us as durable as the everlasting hills which surround it. Like the waters of the Lehigh and the Delaware, whose trail (Traill) enriches distant parts of the State, our memories will converge from the re-

motest regions to this ever-green (Green) spot in the history of our Society.

Dr. Gross, of Philadelphia, then moved to meet every alternate year at Harrisburg. Decided out of order by the chair.

Dr. Gross then offered it as an amendment to the Constitution. Also objected to. Laid over till next year.

Dr. W. H. Pancoast then followed with the reading of a paper relative to a new operation for ununited fracture of the tibia. Having a case of ununited fracture of the tibia, where, in spite of every method heretofore employed, firm union could not be obtained, he finally, in preference to amputation, as desired by the patient, broke the fibula, having previously weakened it by holes bored with a gimlet, and forced the ends to override, so as to enable the widely-separated ends of the tibia to come in contact. This resulted in a firm bony union, and gave a limb capable of being walked upon.

He also detailed a new method for the treatment of fractures of the femur by means of a chair,—the patient being in a sitting position. When lying upon the back, involuntarily the muscles evert the toes and limb, and thus prevent the broken ends of the bone from coming in contact. But by drawing the patient up so as to rest upon the ischial protuberances, the action of the muscles is to invert the toes, and this brings the ends into apposition.

Both papers were referred to Committee on Publication.

A report from the Treasurer, Dr. B. Lee, was presented, showing a favorable balance in the treasury. Referred to Auditing Committee of Drs. Pollock, Weidman, and Bruce.

Dr. Atkinson, Chairman of Publishing Committee, presented his report, which showed that twelve hundred copies of the last year's Transactions had been printed.

Dr. Sibbet, Chairman of Committee on Medical Legislation, reported progress, and requested that the Committee be continued, with power to fill vacancies, which was granted.

Dr. R. J. Levis, of Philadelphia, was appointed by the chair to deliver the address on Surgery, Dr. Wm. Pepper, of Philadelphia, the address on Medicine, and Dr. Joseph Coblenz, of Reading, the address on Obstetrics, for 1875.

This was followed by the reading of an abstract of a voluminous paper, by Dr. J. Solis Cohen, of Philadelphia, on tracheotomy and its relation to croup, which he had read January 14, 1874, before the Philadelphia County Medical Society. Referred by that body to the Medical Society of the State of Pennsylvania.

The paper in question originates from the published statistics of over five thousand cases of tracheotomy in croup, gathered from sources in both Europe and America, and treats at length on the following points:

1. The indications for the operation.
2. The points of importance connected with the operation itself.
3. The after-treatment of the disease and of the surgical wound; and
4. The casualties which prevent recovery.

Among the statistics given is a very remarkable table of successes at a very early age, all of them in cases under two years of age; one, indeed, at as early a period as six weeks.

Dr. Cohen does not adhere to the idea that croup is identical with diphtheria, though he admits a relation analogous to that which typhoid pneumonia has to pneumonia.

He thinks that there is a peculiar systemic poisoning in diphtheria which is not present in sthenic croup; his paper is based, however, upon both forms of the disease, considering the demands for tracheotomy to be equally imperative at certain stages.

The doctor also states that not a single case is recorded of recovery after tracheotomy for diphtheria in the adult, accounting for this by the supposition that the comparatively large size of the larynx in the adult does not entail the danger from suffocation that is met with at a similar stage of the disease in the infant; therefore the blood-disease progresses to a fatal issue before there is much mechanical interference with respiration.

Time will not permit of further pursuing the doctor's line of argument for and against tracheotomy in croup, but, in conclusion, we give the rules which he deems safe to adopt:

1. That there are no insuperable contra-indications to tracheotomy in croup.
2. That the administration of an anæsthetic is admissible in performing the operation for the purpose of controlling the child's movements, but should be used with great caution.
3. That a careful dissection should be made, and hemorrhage arrested before incising the windpipe, whenever there is at all time to do so.
4. That the incision should be made into the trachea as near the cricoid cartilage as possible, to avoid excessive hemorrhage and subsequent accidents which may occasion emphysema.
5. That a dilator should be used, or a piece of the trachea be incised, if there is any difficulty in introducing the tube.
6. That the tube should be dispensed with as soon as possible, or altogether if the case will admit of it.
7. That assiduous attention should be bestowed upon the after-treatment, especially that of the wound, and that a skilled attendant should be at hand promptly for the first twenty-four or forty-eight hours immediately after the operation.

Entire paper referred to Committee on Publication. Committee on Unfinished Business, reporting no items, were dismissed.

The next thing in order was a paper offered by Dr. J. M. Junkin, of Easton, which was read by the Permanent Secretary.

Case in which Life was Saved by Transfusion.

Some years ago I saved the life of a patient by transfusion. As no account of the case has been made public, I lay before you the simple means I used, which proved successful, thinking they would be valuable to other physicians under similar cases.

I was called to attend Mrs. F. about 10 P.M.; found the patient flooding fearfully, from abortion at about six weeks; she was much prostrated from the loss of blood; pulse scarcely perceptible at wrist.

I immediately stopped the blood by a tampon of soft rags, removed pillows from beneath the head, gave stimulants, but the patient still continued to sink; then raised the foot of the bed to retain all blood the patient still had in the brain, and continued this elevation of the patient until she had to be held to prevent her head from pressing against the head of the bed; pulse still feeble, not perceptible scarcely, even at carotid artery.

I then said there was no chance of saving her life, except by giving her more blood, and that from another person, upon which her husband immediately offered his arm; but now another difficulty presented itself: how could we transfer this blood? No instruments at hand, and some distance in the country, and every second shortening the patient's life.

Asked for a syringe; was brought one, a glass, female, with a curved neck, and a bulb on the end of it; at first, thought it would not do, but remembering glass would melt, ran to the fire, thrust it in until softened, drew it out into a slender tube, broke off the end to a proper size, then placed it on the fire to smooth the end, then back to my patient; tied up the husband's

arm, drew several ounces of blood; then told him to place his finger on the orifice, filled the syringe, opened a vein in the arm of the patient, and forced as much blood as possible therein. About two ounces passed in. It was not necessary to repeat this operation, the husband's blood being of a very rich quality, and in a few minutes the patient revived, pulse slowly increasing; by daylight was able to lower the bed a little at a time to its level, and in a few hours to place a small pillow under her head.

The recovery was then rapid and complete. A little more than a year after, I delivered the patient of a large healthy child.

Referred to Committee on Publication.

Committee on Memorial for a new Insane Hospital, represented by Dr. John Curwen, of Harrisburg, reported as follows. A memorial had been prepared and extensively circulated, as the Society desired. A bill had passed the Legislature, which would be signed by the Governor. Also another bill had passed this week, but was directly in opposition to the views of the Society.

He requested the entering of these on the minutes, and the continuance of the Committee, which was granted.

After some remarks from Dr. Green on the Alms-house Insane Department of Northampton County, Dr. Wood, of Pittsburgh, moved that said Northampton County Medical Society be requested to furnish copies of the report of the Committee on the Condition of the Insane in the County Almshouse to the different county Medical Societies of the State, which motion was carried.

A resolution of amendments to the Constitution, to make it harmonize in all its parts with amendments adopted to this session, was offered by Dr. Stetler, and carried.

The following was then offered by Dr. Curwen:

Resolved, That the Committee on Publication be requested to examine carefully the Constitution and By-Laws of this Society, in order to arrange the phraseology and make such modifications as may be necessary to place the whole in a connected and harmonious form. Carried.

The Treasurer's accounts were reported correct by the Auditing Committee, who were then discharged.

Mr. Seamen, on motion by Dr. Lee, was then permitted to exhibit and explain a wheeled crutch and some splints.

Mr. Molesunth was also permitted to exhibit his dilators, uterine syringe, etc.

The Corresponding Secretary's report was then read by the Permanent Secretary.

It showed the addition of several new county Medical Societies. Also the report of the majority of Censors in the case of Dr. Findley and the Blair County Medical Society.

A minority report on this subject from one Censor was then read by the Secretary, but negatived by the President, as he decided the majority report final.

Dr. Crawford appealing from the decision of the chair, the question was put, but the majority sustained the President.

Dr. Curwen then moved that one member be appointed to prepare a report on Hygiene, and also one on Mental Disorders, such report to be read each year before the Society.

The following gentlemen were then appointed by the President: Dr. B. Lee, of Philadelphia, on Hygiene; and Dr. John Curwen, of Harrisburg, on Mental Disorders.

The Society then adjourned.

THIRD DAY.

The Society assembled in the Reformed Church, at 9 A.M., the President in the chair. The first thing

in order was the reading of the minutes, which were approved.

The following was then offered by Dr. John L. Atlee, of Lancaster:

Whereas, This Society has heard with great regret of the death of our ex-President, Dr. Wilmer Worthington, one of the earlier proposers of the formation and organization of this Society;

Resolved, That in the death of Dr. Worthington the medical profession has lost one of its brightest ornaments, the people of the State one of their most generous and actively humane benefactors, and society the intercourse of a highly cultivated Christian gentleman.

Resolved, That this resolution be communicated, with our sincere condolence, to the family of Dr. Worthington. Unanimously carried.

A resolution to the effect that the thanks of the Society be returned to the Reformed Church for the use of the chapel, to the Trustees of Lafayette College for the use of their beautiful Pardee Hall, and for the courtesies of the President and Faculty during our stay at Easton, was offered by Dr. Jas. King, of Pittsburgh, and unanimously adopted by the Society.

On motion of Dr. Green, the following resolutions were read and adopted;

Resolved, That the thanks of this Society be presented to all its officers for the faithful manner in which they have attended to the duties of their respective offices.

Resolved, That the thanks of this Society be presented to the reporters of the proceedings of our meeting, and the editors of the papers—*The Free Press* and *Evening Express*—for the publication of the same. Adopted.

Dr. Curwen then moved that it be resolved that the Medical Society of Pennsylvania earnestly urge upon Congress the passage of the bill, now before them, to give increased rank to the medical corps of the United States Army, and thus open it to appointment and promotion.

Dr. Crawford moved that the thanks of this Society be tendered to the Northampton County Medical Society, and to the citizens of Easton, for their kindness and courtesy extended to us during our stay with them.

Both motions agreed to unanimously.

Then, with a few well-chosen and pleasing remarks from the President, the Society adjourned, to meet on the second Wednesday in June, 1875, at Pottsville, at 3 P.M.

GLEANINGS FROM OUR EXCHANGES.

HERPES GESTATIONIS.—Dr. L. Duncan Bulkley, in the *American Journal of Obstetrics* for February, 1874, gives an able and interesting paper upon a rare and peculiar affection of the skin, which he describes under the name of herpes gestationis. An accurate report of a case which came under his observation is presented, as well as an analysis of eight other cases which have been noted in literature. The disease consists in the development of erythema, papules, vesicles, and bullæ, attended with intense itching and burning, commonly grouped, but not following any special nerve-tracks, appearing generally on the extremities, and afterwards involving the greater part of the body. It is an affection directly dependent upon the gravid state of the uterus. It may appear at any period of gestation up to the seventh month, and usually continues until after delivery. It does not terminate at once, but slowly retrogrades, by the development of fewer and fewer vesicles, rarely remaining, however, as long as a month after delivery. The disease is non-febrile. The eruption may occur very early in pregnancy, and is apt to

return with succeeding gestations. It is sometimes accompanied and followed by other neurotic troubles, as urticaria, neuralgia, etc. The disease must not be confounded with eczema.

The treatment which Dr. Bulkley employed with success consisted in strong tonics, with antipruritic local applications. Iron, quinine, strychnine, and arsenic were used from time to time, together with a dietary regimen, consisting of a meal of oatmeal or bread and milk just before retiring. The recumbent posture was also insisted upon. Locally, a wash composed of *pix liq.* 3ii, caustic potassa 3i, water 3v, one drachm of which is to be diluted with four ounces of water, was used with benefit in allaying the itching from which the patient suffered.

Dr. Bulkley adopts the term herpes gestationis, proposed, we believe, by Mr. Milton, of London, embodying, as it does, the clinical characters of the eruption, and at the same time denoting the sex and condition of the patient in which it occurs.

DOUBLE ANEURISM OF THE FEMORAL AND POPLITEAL ARTERIES (*The Lancet*, April 11, 1874).—Dr. Thomas Diver reports a case of aneurism in the femoral artery just below Poupart's ligament and in the popliteal. He ligated the external iliac artery. Gangrene of the part followed, and necessitated amputation at the lower third of the thigh. This was followed by entire recovery.

NOTES AND QUERIES.

"No, Betsy, drink fair, wotever you do."—*Sairey Gamp*.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

As a subscriber, I feel the right to scold you roundly for articles in the last two numbers.

Why will you persist in saying that the staff of the Pennsylvania Hospital is responsible for the century-old advertisements which seem to bother you so much? You know as well as anybody that the staff has never had anything whatever to do with them.

So far as inquiry can be made, no member of the staff is able to trace a private patient as coming to him through the advertisements, while on the contrary all classes of persons have been led by them to seek the proper officers and to find the right way to avail themselves of the charity of the hospital.

In the guise of a "Slowtown" letter you admit a mass of common but none the less insufferable cackle about Philadelphia—its trade, its schools, and everything about it going to the devil generally.

Now, if a doctor has any power of observation whatever, who knows better than he that [all this is unmitigated nonsense? A closet-man might, by repetition, be made to believe it, but a doctor who drives and walks through every section of the city knows better. Philadelphia has its ups and downs, like every other place, but its general progress in growth, and necessarily in trades and occupations, is truly marvellous. With all its defects, many exceptional things, when contrasted with other cities, can be claimed and proved in its favor. Who better than a physician, for example, can appreciate the way in which its working-people are housed? Could this be so if there was nothing for them to do?

Now, Mr. Editor, don't foul your own nest any more. Write us up instead of down. Protest against the bad, but credit us with the good. Don't growl all the time, but let us understand that when you do growl it means something.

Yours truly,

To scold is generally considered the especial prerogative of maidens soured by time and disappointment. In the above letter there is a sort of recklessness as to facts, and especially as to common sense, which would indicate such an origin. We think most of our readers will agree with us, however, that the internal evidence is very strong that it was written by one of the Pennsylvania Hospital staff, for it is doubtful if, outside of the staff, any one could be found to defend the advertisement. At any rate, the letter must have been inspired by members or a member of the body concerned, and we think "our growl must mean something," when the rulers in Israel are brought by it to appear at the bar of public opinion. Our correspondent's defence is so original that he will find it all anticipated, and, as we think, demolished, in one of our earlier editorials, but certainly he must be trading upon the supposed imbecility of his readers when he

intimates that a man is not responsible for the *permitted* use of his name. In the orthopaedic advertisement recently published in our columns Dr. Sinkler's name is conspicuous by its absence,—an absence due to his having objected to its being there, before, be it said to his credit, the *Times* had published a word upon the subject. Since we have ventilated the matter, Dr. Hunter, one of the out-patients' staff of the Pennsylvania Hospital itself, has requested his name to be withdrawn from the advertisement, and his request has been complied with by the Board of Managers. In the face of these facts it certainly requires a good deal of buccal development to assert soberly that the staff are not responsible.

We never have in any way admitted a "mass of cackle" about Philadelphia generally, unless one sentence makes a mass. We know as well as our correspondent that it is probably the most comfortable city in the world, but we also know as well as he does that the tender-hearted anti-progressionists, of whom he seems to be a type, have been as a nightmare upon us, and have driven very much of the best talent in all businesses out of our city, have destroyed its commerce, and banished its literati. The recent revival in trade and life is due to the discontented—the growlers; and all we hope for is that the strength of our medical schools is not so sapped by contented glorying in the past that the growing element of discontent cannot restore their former prestige.

No doubt the oxen of the Aegean stables upbraided Hercules with fouling their nest, when he stirred up the mighty mass of filth and let loose the mephitic odors; but let us say in brief to our correspondent that the nest is fouled not by those who try to cleanse it, but by those whose nostrils by habit have become so used to the odor that they do not perceive it, and who sit quiet in the old places while power and supremacy are slipping away; who morning and evening dote upon their greatness, whilst the world is laughing at them, and who only raise their voices when disturbed in their lethargic slumbers.

We intend, if possible, to write Philadelphia up, but not by singing the old time-worn lullabies of her ancient greatness, her present perfections, and her wonderful homes for working-people. Rather let our note be some battle-cry, which shall awaken the sleeping giant to a sense of the necessity for effort.—*Ed. P. M. T.*

OBITUARY.

At a called meeting of the Zanesville Academy of Medicine, held Saturday, May 2, to take action in relation to the death of its late Fellow, Dr. Jno. G. F. Holston, Sr., which took place at Washington, D.C., May 1, 1874, the following resolutions were adopted:

That we, whose occupation has been to relieve human suffering, are reminded that the time must come when our places on earth shall be vacated. Therefore,

Resolved, That in the death of Dr. Holston the Zanesville Academy of Medicine loses one of its prominent members, and the profession at large an eminent physician and surgeon of extensive professional and literary culture, ripe in experience and accurate judgment; and society a warm-hearted, genial, and generous member, whose life has been mainly devoted to the good of his fellow-beings.

Resolved, That we attend the obsequies of our deceased Fellow, in a body.

Resolved, That we deeply sympathize with the family and relatives of the deceased.

Resolved, That the Corresponding Secretary transmit a copy of these resolutions to the family, the city press, and the medical journals.

C. C. HILDRETH, Chairman.

A. E. BELL, Secretary *pro tem*.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 12 TO MAY 18, 1874, INCLUSIVE.

TOWN, F. L., SURGEON.—To proceed to Fort Sill, Indian Territory, and on arrival report by letter to the Commanding General Department of Texas, for assignment, so much of S. O. 96, c. s., A. G. O., as directs him to report in person, having been revoked. S. O. 105, A. G. O., May 13, 1874. Relieved from duty at Fort Preble, Me., S. O. 98, Mil. Div. of the Atlantic, May 14, 1874.

McCLELLAN, ELY, ASSISTANT-SURGEON.—To take station at Louisville, Ky., and from that place visit the towns and localities at which cholera prevailed during the year 1873, as designated in instructions given him by the Surgeon-General. S. O. 103, A. G. O., May 11, 1874.

PATZKI, J. H., ASSISTANT-SURGEON.—Assigned to duty at Fort Fred. Steele, Wyoming Territory, S. O. 65, Department of the Platte, May 9, 1874.

HOLDEN, LEVI H., SURGEON (Retired).—Died at Vineland, N.J., on May 12, 1874.

SATURDAY, MAY 30, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON A CASE OF CEREBRAL RHEUMATISM, SO CALLED.—USE OF COLD BATH.

BY H. C. WOOD, M.D.,

Clinical Lecturer on Diseases of the Nervous System in the University of Pennsylvania.

GENTLEMEN,—A few days since, upon entering the ward my attention was instantly attracted by the expression upon the face of a patient. He was a young, temperate Irishman, twenty years of age, and of vigorous physique, who had passed through a severe attack of inflammatory rheumatism without cardiac complications, and was suffering from a relapse, which first appeared as a subacute inflammation of the knee. I had not seen the man the previous day, but I find in the note-book of my very able resident, Dr. Bruen, the following:

"Second day of relapse. This morning an acute inflammation of the wrist-joints has set in; the fever is very high; temperature in the axilla 104° Fahr.; ordered potassii bicarb. gr. xx every two hours."

As we walked to the bed, in reply to a question, "What ails our rheumatism patient?" Dr. Bruen said, "Nothing, unless it be pericarditis. When I saw him at 10.30 A.M. there was much less inflammation of the joints than the preceding morning, and although his temperature was as it had been, 104° Fahr., and, as I thought, a pericardial friction-sound could be heard, yet the man was doing fairly: perfectly rational, with a good pulse." It was now about half-past twelve, and our patient was apparently dying. The pulse was between 160 and 170, exceedingly feeble and thready; the pupils strongly contracted, though not to pin-points; the respirations fifteen per minute, exceedingly irregular, mostly deep, jerking, and interrupted; the skin pale and dry; the consciousness completely lost, violent shaking and shouting in the ear only eliciting a few grunts; the temperature in the axilla $108\frac{1}{2}^{\circ}$ Fahr.; the wrists pale, and no signs of pain elicited by violently moving them. On ausculting the heart I could find no murmur; the first sound was very feeble, somewhat prolonged, and the second, sharply accentuated.

It was very evident, gentlemen, that if this man were left to nature he would die, and that most speedily. As a contrast to what happened under treatment in the man now hale and hearty before you, and as portraying the natural history of this disorder, let me read you the following account of a case that occurred here a few weeks since, and was in a measure left to nature:

Charles M., æt. 40, of German birth, was admitted to the hospital March 6, 1874, suffering from acute articular rheumatism. On March 11 he was seemingly much better, the pain having left him, and the redness of the joints diminished; but the resident physician in the morning noticed that he was very drowsy. At 10 P.M.

the resident physician was summoned by the nurse, who said that the man had apparently taken an over-amount of opium, of which large medicinal doses were being given him. The man was found unconscious, lying quiet and motionless, with slow, rather deep respirations. He was aroused with difficulty by vigorous shaking, and was able to put out his tongue, but could not speak. He had a dull, dazed expression, and appeared like a man who was mildly narcotized, so that the resident, agreeing with the nurse, ordered strong coffee and watching.

At midnight the doctor in charge was again sent for. The patient had lost the power of swallowing, and could not be aroused at all; but he showed signs of uneasiness when roughly pinched or pricked with a pin. His respirations were 18; pulse 160. Eight ounces of blood were taken by cups from the back of his neck, three drops of croton oil administered, and external counter-irritation freely made. About 1 A.M. the resident's attention was attracted to his intensely hot skin, and on thermometrical examination the temperature was found to be $110\frac{3}{4}^{\circ}$ F. It did not fall below this up to death, which took place about 4 A.M. A careful autopsy was made, but no lesion whatever could be found, unless it were a doubtful congestion of the brain.

In order to treat my case intelligently, it was of course necessary to determine first the nature of the frightfully sudden exacerbation which threatened his life. In the course of inflammatory rheumatism there happens every now and then exactly what occurred in our patient,—an apparent disappearance of the external symptoms, a sudden rise of temperature, the development of the most severe nervous disturbance, all ending in death. This is the so-called "cerebral rheumatism." What is its essence or nature? What the sequence and relation of its phenomena? Of the real essence or nature of rheumatism we know scarcely more than did our asserted simian progenitors before Adam was. We can, however, I think, say, in accordance with our clinical knowledge, that there is in the system a something, a poison, an irritation,—in our ignorance one term is as good as another,—an influence which flits from part to part, seemingly subject to no laws and perfectly whimsical in its movements.

Is cerebral rheumatism, then, simply the result of a retrocession of this agent to the nerve-centres? are the unconsciousness, the motor, respiratory, and circulatory disorders, simply due to a direct action of the rheumatic influence upon the nerve-centres? Gentlemen, I say no; and I hope to convince you of the truth of this denial. If the spinal cord be cut just below the origin of the respiratory nerves, and the animal, by being wrapped in cotton or by being placed in a warm atmosphere, be protected from the great loss of heat by radiation which follows the paralysis of the peripheral vessels, a rise of temperature occurs, and progressively continues until the animal dies in a frightful fever. What does this mean? To my mind, it means that there is an inhibitory heat-centre at the base of the brain, or, in other words, a ganglion, which controls and regulates those chemical changes whose outcome is "animal heat." The circulation is greatly lessened in its activity by the section of the cord, and it seems hardly probable that the stagnant blood-current of

vaso-motor paralysis should of itself cause a rise of temperature. I have, however, not time this morning to reason out this matter before you. So far as concerns the present case, the only lesson of importance is distinctly taught by the experiment, —namely, that there is somewhere in the brain a centre which controls the heat-production of the body directly or indirectly, and whose paralysis is followed by violent fever.

With this light it is easy to explain the high temperature which was present in our case. The rheumatic poison or influence did so affect this centre that upon the second day of the relapse the temperature rose to 104° F., and upon the third day, the paresis of this centre deepening into paralysis, the axillary temperature went to $108\frac{4}{5}^{\circ}$ F.

Unfortunately, we have no observation to show whether there was a palpable transfer of the rheumatic irritation from the joints to this centre. There may or may not have been.

Having found the method in which the temperature was in this case elevated, we have, gentlemen, discovered how the nervous symptoms were produced, for I insist that they were not the result of rheumatic influence acting upon the brain or its membranes, but were solely due to the excessive heat. Do not mistake me. I do not claim that there never is a "cerebral rheumatism" in which the cerebrum is directly affected by the rheumatic agent, but I maintain that in the present case this did not happen; that the excess of heat was the poison, and that the reason the rheumatic influence was so completely lost in the joints was not so much that it had migrated from them as that it was overwhelmed and imperceptible amidst the general wreck. I may further add that, in my opinion, very many of the cases of cerebral rheumatism have the same pathology as the present. The proof which I shall adduce in favor of the view enunciated may be summed up in the following propositions: First, that the temperature present would of very necessity cause nervous symptoms exactly like those which were actually present in our patient; second, that removal of the excessive heat was followed by instantaneous relief of the nervous symptoms.

First. As is well known, exposure of man to heat produces a disease known as sunstroke; and I call your attention to the similarity of the symptoms of that disease with those of the case before us. The suddenness and the terrific force of the onset, the biting, dry skin, the high temperature, the contracted pupil, the unconsciousness, the irregular breathing, and the exceedingly rapid pulse, are all common features, and are almost the sole features of each disease: in the one case you see a counterpart of the other. I have elsewhere proven that the poison of sunstroke is heat. Time fails, and I cannot go over the experiments in detail, but can only sketch a few prominent features of my investigation. It was found that heating produces in animals a sunstroke exactly simulating the disease as seen in man. As in experimenting it was possible to eliminate all other factors, it was distinctly proven that heat is the sole cause of thermic fever. Further, by a simple mechanical contrivance the brains of animals were

heated without the remainder of the body being affected, and the same sudden loss of consciousness, contraction of pupils, and respiratory disturbance as are present in sunstroke were developed just at the time when the brain reached the point respectively attained in thermic fever in the various species of animals employed. It was found that a temperature of 113° – 114° F. was fatal to the brain of a cat. The normal temperature of a cat is 102.5° F.; of a man, 98.5° F. The brain of the cat is probably less sensitive than that of man, because less highly organized. In our patient we found, late in the case, that the rectal temperature was two degrees higher than the axillary, and without doubt his brain-temperature when first seen was at least 110° F.,— 11.5° F. hotter than normal. In the cat a cerebral heat-increment of 6° F. will cause violent convulsions, with unconsciousness, and one of 11° F., complete brain-paralysis.

Evidently, our first proposition is proven. By reasoning similar to that which has been gone through before you, I came to the conclusion that our patient was dying of heat, and determined to cool him at all hazards, and, as the surest and most rapid means, to employ the cold bath.

The following is the record made at the time:

1.24 P.M.—Patient put in a full bath at 60° F.

1.25 $\frac{1}{2}$.—Shows signs of consciousness; will put out the tongue when loudly asked to do so.

1.27.—Seems to recognize the bath is very cold, and struggles to get out.

1.30 $\frac{1}{2}$.—Man has a fair degree of rationality. He has been in six minutes and a half, and now ordered to be taken out at once.

One minute after the bath.—The patient was partially wiped and laid directly upon a gum blanket, and covered only with a sheet, in a room whose temperature was about 65° to 70° F. He has just received a hypodermic injection of six grains of quinine.

Three minutes.—Temperature, in axilla, 94° F.; in mouth, $105\frac{3}{5}^{\circ}$ F.

Eight minutes.—Temperature has been steadily falling; is now 103° F. in mouth. The man has become perfectly rational, and answers to his name.

Pain and sensibility have returned somewhat to the wrist. Ice-bladders were applied to head ten minutes after bath. The attendants state that he passed a very little urine at 11 o'clock; bladder is now entirely empty.

Twenty-four minutes.—Temperature in mouth $104\frac{3}{5}^{\circ}$.

2 P.M.—Pulse 140, weak. One-half fluidrachm of tincture of digitalis, with two ounces of raw whisky, were given.

2.45.—Temperature in mouth 101° , in axilla 102° , in rectum $102\frac{3}{5}^{\circ}$.

4.15.—Digitalis and whisky were repeated, but were immediately vomited. Pulse 140; temperature $101\frac{3}{5}^{\circ}$. No urine had yet been secreted into the bladder. He was cupped ten ounces of blood over the kidneys. Ordered an enema, also \mathfrak{z} ii of acetate of potassium ordered every two hours, with two ounces of infusion of digitalis applied on cloths to abdomen. Small quantities of milk and lime-water were given at intervals.

8 P.M.—The patient says he feels very much better; recollects nothing of the past, excepting that in the morning he was very dizzy, and just afterwards became unconscious. Application of digitalis renewed. Pulse 128, temperature $102\frac{1}{5}^{\circ}$.

12 midnight.—Pulse 116, much stronger; temperature $99\frac{1}{2}^{\circ}$. Complains of feeling cold, but in other

respects is better. Has passed about a pint of urine. Since his bath he has been lying on the gum blanket, covered only by a sheet, as at first. He is now ordered to be put into a warm bed, and covered with blankets. Ice still kept applied to head. Other treatment continued, excepting the digitalis-poultice.

April 9, 9 A.M.—Is much better. First sound of heart very weak; second sound very strongly accentuated, both pulmonary and aortic. There is no murmur.

Was ordered to take, during day, \mathfrak{ss} citrate of potassium, in one-half pint of water, every two hours; ten drops tincture of digitalis, and two grains quinine, every three hours; one-half pint milk every four hours. Temperature $100\frac{1}{2}^{\circ}$, pulse 120.

At 12, temperature $101\frac{1}{4}^{\circ}$, pulse 124.

3 P.M.—Temperature 101° , pulse 120.

8 P.M.—Treatment all carried out, excepting the milk, which caused great nausea and vomiting; it was therefore given one ounce at a time, and about one pint, with eight ounces of beef-tea, was retained during the day. Medicine was all retained without difficulty. He has passed urine freely during the day,—about three pints in all. Temperature $102\frac{1}{2}^{\circ}$ F., pulse 122. He complains of severe pain in wrist-joints and in the shoulders. Treatment continued during night, when awake. Five-grain Dover's powder ordered; the same dose to be repeated at 12 o'clock, if awake.

April 10, 9 A.M.—The patient slept during the past night, for the first time since the 8th. Took his medicine without any nausea being experienced. Says he feels much better. Ice-cloths to head discontinued; other treatment continued. The condition of joints of wrists and shoulders is about the same as on the morning of the 8th: they are very swollen and painful. Pulse 120, temperature 101° F.

6 P.M.—Condition as in morning. Has taken one quart of milk during the day. Temperature $100\frac{3}{4}^{\circ}$ F., pulse 116.

April 11.—Temperature $100\frac{3}{4}^{\circ}$ F., pulse 92. Quinine sulph., fifteen grains daily, ordered. Digitalis and the potassium salt continued.

April 12.—Is very much improved. Pulse 96, temperature 100° . Citrate of potassium ordered every three hours; thirty drops tincture of digitalis in twenty-four hours.

April 14.—Feels very little pain in joints, has good appetite, and looks, indeed, almost well. Citrate of potassium discontinued. Iodide of potassium, ten grains, t. d.; tincture of chloride of iron, gtt. xx , t. d. Quinine continued. Temperature 99° , pulse 72. Tincture of digitalis stopped.

May 4.—From the time of previous note he steadily progressed towards entire convalescence under a tonic treatment, and has been for some days going about freely. To-day he is to be discharged, perfectly well. There is no cardiac lesion whatever.

Let me call your attention, gentlemen, to the rapidity with which, under the influence of the cold bath, the symptoms abated in our patient. He was not in more than a minute and a half before he exhibited very distinct signs of returning consciousness, and in three minutes had sense enough to attempt to get out of the tub. What could the bath do to affect the man so much but withdraw the heat, which, as you know, we have found to be a poison to the nervous system? That the heat was withdrawn, the thermometer proved. If the drowsiness had been due to simple congestion of the brain, very certainly would the bath, by driving the blood from the surface, have increased the trouble. It has been distinctly proven by various

physiologists (see paper by Dr. T. Lauder Brunton, St. Bartholomew's Hospital Reports, vol. vii.) that heat directly increases the rapidity of the heart's action, and in our patient the intensely rapid pulse became slower under the influence of the bath. In what way could the bath do this, unless it were by the withdrawal of heat from the body? Indeed, without further discussion, I claim that the above record establishes my second proposition, and that it has been proven that heat was, in this case, the agency that would have hurried our patient into the grave had it not been for the friendly bath-tub. The sudden change from death to life was, to me, intensely interesting, not only because the stake was a human life, but also as a matter of a wider scientific interest.

I have often produced in the lower animals the symptoms which were present in our patient, and, plunging the animal into a cold bath, watched the fall of bodily temperature, the rise of temperature in the water, and the disappearance, *pari passu*, of the nervous symptoms.

The experiment upon man and the experiment upon the lower animal, exactly similar in their course and results, furnish a new demonstration of the falsity of that narrow and ignorant though popular philosophy which looks upon man as something physically apart from the rest of the living creation, and fails to see that, bone of its bone and flesh of its flesh, the human is subject to the same influences and dominated by the same laws as the animal.

There is one point in the treatment to which I want to call your attention, namely, that the patient was taken out of the bath before his temperature had nearly reached the normal point. I did this because I have noticed in animals that the temperature often continues to fall after removal from the bath, and, if the latter be continued too long, may go down far below the normal point. Thus, I have exposed a pigeon, having a normal temperature of $109\frac{1}{2}^{\circ}$, in a hot-air chamber, and, when the temperature had risen to $117\frac{1}{2}^{\circ}$ F., plunged the bird into water; taken it out when the temperature was $109\frac{1}{2}^{\circ}$, and in the course of twenty-five minutes seen the temperature fall to 96° , although the bird was put in a warm place. No doubt some of this excessive fall was due to the wet feathers; but I have seen the same thing in quadrupeds, and believe that in the use of the bath in cases like the one now under consideration there is a possibility of carrying the effect too far, and of actually depressing, to a fatal extent, heat-production. In ordinary fevers this danger is, of course, less than when the original rise of temperature has been from a transient cause.

In most cases of cerebral rheumatism there is a very manifest tendency for the reduced temperature to rise again, and the question is a most vital one why, in the present instance, no such inclination showed itself. Very probably the hypodermic injection of quinine had some decided influence, since, although the alkaloid has very little effect in reducing normal temperature, it does appear to exert a very decided antipyretic action when the temperature is above normal. I believe, however,

that the prevention of relapse was largely due to what seems to me the boldest part of the treatment. Remember, the man was suffering from acute inflammatory rheumatism, and, a few hours before, a council of our most experienced residents had diagnosed commencing pericarditis; yet the patient was plunged into a cold bath, taken out of it, and, without being wiped dry, laid upon a cold rubber blanket, covered only with a sheet, and so left in a cool room for many hours. What seemingly could be better calculated to bring on fatal internal rheumatic inflammations? Yet no pericarditis developed itself; only a steady convalescence, from a condition formerly considered almost of necessity fatal.

What was the reason? I believe it was partly because the circulation was steadied by large doses of digitalis, but chiefly on account of the high temperature. How can you chill a man whose body is burning up, and whose circulation is filling every extreme arteriole and capillary under the greatly increased arterial pressure caused by the digitalis? I do not want, however, to see you recklessly follow the treatment of the present case, at least so far as concerns the after-exposure of the patient.

"One swallow does not make a summer," and in departing so widely from the old paths we are treading untried ground. If I had been on the spot, this exposure would not have been so long continued. When the temperature showed indications of falling below 102° , the man ought to have been placed in bed and lightly covered.

The case, gentlemen, would afford much food for further discussion. It would be especially interesting to study the use of digitalis as a stimulant, in this connection; but our hour has expired, and the record must be left to tell its own story.

ORIGINAL COMMUNICATIONS.

THE LOCAL TREATMENT OF PULMONARY CAVITIES BY INJECTIONS THROUGH THE CHEST-WALLS.

BY JAMES H. HUTCHINSON, M.D.,

One of the Attending Physicians to the Pennsylvania Hospital.

THE attention of the readers of the *Philadelphia Medical Times* has been recently called to this method of treatment of the third stage of phthisis pulmonalis, by Dr. William Pepper, who resorted to it in three cases with great advantage, he thinks, to the patients. By a coincidence which is not infrequent in medicine, Dr. Mosler has been trying the same experiment in Germany, and has published an account of it, which reached this city after Dr. Pepper's paper was in press. It is not necessary to give details of these experiments further than to say that Dr. Pepper injects into the cavity, by means of Dieulafoy's aspirator, from four to ten minims of a very dilute Lugol's solution of iodine (M^{iv} to f^{ij}), and that Dr. Mosler, after making a perforation, —the means by which this was done are not given, —introduced a silver drainage-tube, which appears to have been allowed to remain in the body until the death of the patient, four months after the

operation. During life, the tube was not merely used to permit the escape of secretions, but also served as an avenue to introduce various medicinal substances into the cavity. We of course recognize a difference between these two sets of experiments, inasmuch as in one the employment of the aspirator probably prevented the entrance of air into the cavity, and in the other this was allowed to take place freely. We cannot, however, regard this as a very important distinction, since there is almost always an uninterrupted communication through the bronchi between excavations in the lungs and the outer air. Moreover, Dr. Pepper says, in concluding his paper, that he should have no objection to use a trocar and canula, and to leave the latter permanently in the wound.

We need not say how cordially we should welcome any operation or remedy which afforded a reasonable hope that it would be found to be useful in reducing the mortality from phthisis, or even in prolonging life after the formation of vomicae. For, although we do not admit that the existence of a cavity is necessarily an indication of a speedy dissolution, we agree with Dr. Pepper in thinking that when the disease has arrived at this stage we possess but little power to stay its downward course. Both of our experimenters speak of their plan of treatment as affording this hope, and, moreover, appear to think that it is novel. It is in these points of view that we propose to criticise it; and first, in regard to its novelty.

In the London translation of Baglivi's *Practice of Physick*, published in 1723, we find the following passage, which we quote just as it is printed:

"A Phthisick arising from an Ulcer is commonly branded as incurable, upon the Plea that the Ulcer is internal and occult, and cannot be cleansed like other external Ulcers. But why do they not make it their Business to find out the true Situation of the Ulcer, and make an Incision accordingly, between the Ribs, to the end that proper Remedies may be conveyed to it? For my Part, I know no Reason why that should lie neglected. About Seven Years ago, when I was at Padua, a Man received a Wound in the Right side of his Breast, that reached to his Lungs; and, employing an able Surgeon, had an incision made between the Ribs to the Length of Six Fingers' breadth, in order to discover the Situation of the Wound in the Lungs, which was perfectly cured in Two Months' Time, with Vulneraries, applied with Tents and with Syringing. Now, Practitioners ought to use the same Piece of Diligence in curing a Phthisical Ulcer in the Lungs, lest the Scroll of incurable Diseases should grow too long, to the infinite Disgrace of the Profession."

As Baglivi's work was published in 1696, we have sufficient evidence in the above that the propriety of establishing a communication between the lungs and the outer air through the walls of the chest, for the purpose of applying remedies directly to the seat of the disease in cases of phthisis, was entertained as early as the seventeenth century. We shall show in the following quotation from a work published in London in 1763, by Dr. Edward Barry, F.R.S., entitled "*A Treatise on the Three Different Digestions*," that the operation was recommended by Hippocrates, and that it was not infrequently done during the eighteenth century:

"When evident marks," Dr. Barry says, "appear in the Sides, all Authors, antient and modern, agree, that an Aperture should be made; and Books of Observation abound with Instances of this kind, where it has been performed with Success. *Hippocrates** constantly directs it either with the *Knife* or actual *Cautery*, not only where the *external Appearances* are evident, but where they are very *obscure*: and seldom seems to doubt of Success, but in very advanced Cases, where the Fluids in general and the purulent Matter collected are degenerated into a putrid eroding State, and where, though a free Discharge is given, yet the Ulcer can never heal. It appears from the Dissection of those who have died of this Distemper, that such Abscesses or Ulcers in the Lungs generally adhere by a large Surface to the Pleura. . . . By this Adhesion of the Lungs to the Pleura, the Parts affected are kept (as if carefully designed by Nature) in a great Measure in a State of Rest and easily admit an Opening into the Cavity; neither if the Operation fails can it be attended with any great Danger, or much accelerate the Progress of the Distemper."

Passing to the present century, we find that substantially the same method of treatment has not only been proposed, but actually carried into effect, many times during the last fifty years. Ramadge reports several cases in his treatise entitled "*Consumption Curable*" (London, 1836). In one of these he introduced a trocar between the second and third ribs, in a line nearly perpendicular to the left nipple. "I kept," he writes, "the punctured place open for about ten days by the introduction of a small piece of catgut properly secured externally, when, finding that the cavity became so contracted through the encroachment made on it by the pulmonary expansion as to preclude all further escape of air, I withdrew it." Dr. Hastings and Mr. Stork† have also reported one case in which a silver tube was first introduced, and, not answering, an elastic gum catheter was substituted for it; and a Mr. Robinson another. The publication of the former led to some little controversy as to the propriety of the operation, Drs. Herbert‡ and Campbell§ maintaining that no good results could be expected from it. We have also abundant proof that the accidental opening of a phthisical cavity through the chest-walls may not only not cause immediate death, but may occasionally lead to an apparent arrest of the disease. Thus, as a consequence of the application of the actual cautery to the chest in a case reported by M. Bricheateau,§ a pulmonary cavity was opened and emptied of its contents. Fifteen months later the patient succumbed to an attack of pericarditis, when the cavity was found partially obliterated. In Canstatt's *Jahresbericht* for 1843, vol. iii. p. 365, will be found a reference to the *Medical Times*, Nos. 60, 171, and 180, in which a writer under the signature of "*Discipulus*" reports two cases of phthisis, in one of which a cure is said to have been the result of a self-inflicted wound of the neck by a would-be suicide, and in the other followed the spontaneous evacuation of a vomica through the parietes of the chest.

These few extracts and references—and they

might be multiplied without difficulty—prove that the operation of injecting pulmonary cavities through the chest cannot be in any sense considered a novel one, and we believe we shall be able to show that it is not one which is likely to result in good to the patient. In the first place, the presumption in regard to its usefulness is against an operation which, after having enjoyed a brief popularity during at least three or four different periods, has been so utterly forgotten that it has been as many times proposed as entirely new, and is certainly against one in which the opportunities for performing it would be so frequent as they are in this. The quotations|| which we have introduced above demonstrate with sufficient clearness that the lung may in many instances be laid bare and punctured without apparent injury to the patient. We are inclined to think that this is by no means uniformly the case. In one of the cases reported by Dr. Pepper a slight hemorrhage followed the introduction of the aspirator; and the same accident occurred in the operations done by Dr. Mosler and Dr. Hastings. We are, moreover, very strongly convinced of the fallacy of the argument that, because punctured wounds of the lungs in healthy individuals generally do well, their infliction upon consumptives is not likely to be followed by bad results. Niemeyer—we believe (for we quote him at second hand)—goes so far as to say that the inflammation excited by wounds of the lungs usually terminates in phthisis; but, admitting that this distinguished physician may push his conclusions as to the nature and origin of this disease to an unwarrantable length, there are certain differences in the anatomy of the lung in health and disease which ought not to be overlooked. Caseous degeneration is not the only change which is observed in phthisis. There is in addition to this, in most cases, a development of connective tissue, the effect of which will be to enlarge and keep open the wound made by the aspirator or trocar, and thus to allow the escape of the contents of the cavity into the pleural sac whenever this is not prevented by firm adhesion; and that cavities are not always protected by adhesions is shown by the occasional occurrence of pneumothorax from their rupture. Moreover, the opinion that injections may be of service in the treatment of phthisis rests, we think, upon a mistaken therapeutic basis. In certain conditions of the serous membranes these are unquestionably useful by exciting inflammation; but a little reflection will convince any one who has abandoned in whole or in part the theory which makes phthisis the result of tubercular deposit that this is the very last thing to be desired in this disease. The object aimed at in the management of phthisis, and especially in those local cases in which Dr. Pepper thinks the injections are most likely to be useful, is to allay inflammatory action, not to excite it. We therefore are unable to see how they can be productive of any good; on the contrary, if they light up an inflammatory process in the walls of the cavity, this will be very likely to extend to the cir-

cumjacent tissue, and thus the disease, which may have been previously held in abeyance, be roused into activity.

In conclusion, we have only to add that we never condemn a plan of treatment on purely theoretical grounds, and will gladly adopt the one under consideration if the result of further experiments shall convince us of the incorrectness of the unfavorable opinion we have formed of it. In the mean time, however, we shall remain in full accord with Dr. Hughes Bennett,* who thinks that the result of all operative interference in phthisis has been "what an intelligent consideration of the pathology of the disease might have anticipated,—a uniform failure."

2019 WALNUT STREET.

AN UNNATURAL POSITION OF THE HEAD A CAUSE OF DEATH FROM CHLORO- FORM AND OTHER ANÆSTHETICS.

BY G. W. COPELAND, M.D.,

Boston.

IN the *Boston Medical and Surgical Journal* of February 26, I published a short article on the "Styloid Muscles and Anæsthetics," in which I referred the cause of impeded breathing during anæsthesia to the action of the styloid muscles closing the glottis. I also pointed out how the difficulty could always be relieved without making traction on the tongue, simply by tilting the head forward in a natural position, so as to relax these muscles and permit the patient to breathe through the nose.

It has since occurred to me that many of the deaths which have resulted from the use of anæsthetics may have been due to the imperfect knowledge that has existed regarding this matter. The difficulty experienced in keeping the air-passages free has, ever since the discovery of anæsthetics, been the most troublesome and dangerous complication attending their use. All authorities agree that obstructed or impeded respiration is a symptom attended with great danger to the life of the patient, and always requires prompt and immediate attention.

Waring, in his book on Practical Therapeutics, sums up the experience of the profession with chloroform, in the following observations: "Watch carefully the respiratory movements, and the color of the cheeks, lips, and eyes. Signs of danger: lividity of the face, stertorous respirations, irregular, gasping respirations, feeble pulse, death-like pallor." His directions are, "Stop the chloroform, open the mouth, draw out the tongue, and watch carefully."

When we consider the ways in which deaths occur during anæsthesia, we see that these signs of danger have not been so designated without sufficient reasons.

Gant, in his *Science and Practice of Surgery*, speaks of death from chloroform as follows: "During inhalation, death may occur in three different ways: by asphyxia, by cardiac syncope, or by coma.

"Asphyxia is indicated by the ordinary symp-

oms, lividity and turgescence of the face, violent respiratory efforts, and cessation of the pulse and of the heart's action."

In cardiac syncope "the patient, after a few inspirations, suddenly becomes pale and faint, the pulse beating almost imperceptibly for a few moments, and then ceasing, although the respirations may continue; death taking place by paralysis of the heart."

"Coma presents the same appearance as asphyxia, but without failure of the heart's action; death resulting from congestion of the brain."

In two of these three modes of death we then see that there is impeded breathing and improper aeration of the blood, as evinced by the lividity of the face. The great mistake up to the present time has been in considering the difficulty with the breathing, a symptom arising from the use of anæsthetics or a sign of full anæsthesia, and not a mechanical obstruction of the glottis from an unnatural position of the head.

The *Lancet* of February 1, 1873, contains a report by the editor of a "Case of Fatal Suffocation from Nitrous Oxide Gas," in which a dentist is related as having administered that agent for the purpose of extracting a tooth. He says "it was not till after the operation was completed that anything unusual happened, but immediately afterwards the face became livid, and the 'features,' it is said, 'commenced to 'swell.'" He refers death in this case to asphyxia.

In a case of death from the bichloride of methylene, which occurred at the Charing Cross Hospital in the practice of Mr. Canton, it is stated that "one nostril was closed by the tumor, thus obstructing respiration, and the patient was subjected to the influence of the bichloride in the sitting posture."

In the *Lancet* for September 6, 1873, the editor, in commenting on a death from chloroform which happened in a dentist's chair at Brighton, the post-mortem showing fatty degeneration of the heart, says, "It is one of those cases when death seems to have followed rigidity of muscle, and it is questionable whether asphyxia may not have helped, as it were, the fatal syncope."

It seems to me very plausible that cardiac syncope may be induced by the momentary closure of the larynx depriving the heart of its natural stimulus in patients suffering from shock or fatty degeneration, or already reduced by disease. It is a significant fact that all the deaths from nitrous oxide gas, and a large number of those from other anæsthetics, have taken place while the patients were in a sitting posture, which would allow the head to fall back farther than if they were lying down, thus favoring the theory that interference with the free action of the lungs may have been the primary cause of death. It must be remembered that closure of the glottis may occur without our attention being directed to those struggling efforts on the part of the patient which would happen were voluntary efforts possible, and the first noticeable symptoms of danger may be lividity of face or death-like pallor.

It may not be out of place here to refer to the many deaths from intoxication, apoplexy, and

* Reynolds's System of Medicine, vol. iii. p. 589.

coma from whatever cause, as being in some instances hastened, and perhaps even produced, by interference with the respiratory functions from an unnatural position of the head.

There is one other point to which I wish to allude, and it is the importance of elevating the head sufficiently to compel the patient to inhale the anæsthetic through the nares entirely. If deep inspirations be taken through the open mouth, the lungs are inflated instantaneously and just as rapidly emptied, leaving a long interval without any of the vapor being in the lungs. If the inhalations be through the nares, it takes a much longer time to inflate the lungs and a much longer time to empty them, leaving no interval. Now, the number of respirations per minute is the same either way: it follows that it will require a longer time to effect anæsthesia through the mouth than through the nose.

It appears evident to me that if attention be paid to the position of the head during anæsthesia from any agent, a greater degree of safety will be obtained than has hitherto existed.

NOTES OF SOME SURGICAL CASES.

BY JOHN J. BLACK, M.D.,

New Castle, Delaware.

FEMORAL HERNIA, AT TIMES SIMULATING STRANGULATION, ACCOMPANIED BY A CLINICAL CURIOSITY.

SATURDAY, November 29, 1873, 11 o'clock A.M., I was summoned to see a lady about 60 years of age; she told me she had had a "rupture" in each groin for a number of years. Never had had trouble until this morning, when she was unable to reduce the one on the left side. Had severe umbilical pain, and the tumor was tender. Had worn a double truss "off and on" for a long time. Upon examination, I found a femoral hernia on each side; the right one normal, the left one presenting a tumor, size of a hen's egg, quite tender, and irreducible after the usual manipulation. I then asked my friend Dr. G. T. Maxwell to see the case with me. I again tried manipulation without success. Then we etherized the patient, and were still unsuccessful. We introduced the needle of a hypodermic syringe, and drew off a little serous fluid, but do not think the bulk of the tumor diminished much. We next gave a full opiate, and our patient was comfortable for several hours. Did not vomit. Again the tumor did not yield to manipulation, very carefully performed, yet the symptoms of strangulation were not decided, and we gave her an opiate, and left her until morning. Then I found her with pain about the umbilicus, and vomiting; and then I made up my mind there was strangulation, and I would have to cut down on the tumor and liberate it. But, after giving her numerous draughts of water, the stomach quieted, pain ceased, and the symptoms were no longer urgent, the sickness and bilious vomiting having been caused by the opiate. The tenderness increased in the tumor; redness appeared, showing a tendency to suppurate. This state of affairs continued increasing until December 10 following, when I made carefully a valvular incision and liberated a large amount of pus. Immediately on opening the tumor there was an escape of the foulest-smelling gas. I supposed at the time I had unintentionally opened the bowel; but later disclosures have taught me to believe that the foreign body hereafter to be spoken

of had penetrated the bowel from within outwardly, and caused the suppuration in the cellular tissue of the abdominal walls, external entirely to the bowel. Poultices were applied for several days, rest enjoined, liquid diet, etc.

One morning, about ten days after this, on visiting her, she showed me a piece of bone, about one and a half inches long, which she had extracted from the opening in the tumor. After this the opening soon healed, and up to this time (April 17, 1874) the hernia has appeared to be "radically cured."

Remarks.—My friend Dr. James Tyson, of Philadelphia, kindly presented the bone to Prof. Harrison Allen for examination, and he pronounced it to be not human, but a part of the rib of a robust-chested mammal of small size. Prof. Leidy first thought it a foetal rib, but, after examining it, was satisfied it was not human. I may add here that the patient was a married woman, and had had two children.

This case is interesting, first, as simulating strangulation, which I believe did not occur at any time during its progress; second, the discharge of the foreign body, which must have been swallowed with the food, and have worked its way through the bowel; and third, as exhibiting the hernia as up to date cured by the inflammation developed in the case.

AMPUTATION AT THE SHOULDER-JOINT FOR EXTENSIVE GUNSHOT WOUND OF THE ARM AND SHOULDER.

Friday, October 31, 1873, I was called down the State by Dr. Kemp to see, in company with Drs. Dunlop, Worrell, and Fromberger, a young gentleman, 23 years of age, healthy, and well built, who, the evening before, had, whilst returning from a duck-shooting excursion, shot himself accidentally with a full load of heavy duck-shot through the upper part of the left arm and shoulder. The bone was shattered nearly to the head; soft parts carried away on top of arm and shoulder, and also part of the skin and muscles of the shoulder posteriorly, leaving the arm hanging by the axilla, vessels, and nerves. He was very weak, and had apparently lost much blood before assistance had been rendered him, but, thanks to the attention of the physicians in charge, had commenced to rally, and was not losing blood. At the time of my arrival, of course, there was nothing to do but to take out the arm at the shoulder-joint, which, with the approbation and assistance of the medical gentlemen present, I did, after the method of Larrey, modified somewhat, inasmuch as the soft parts were so much lacerated and destroyed. I was compelled to draw the parts together posteriorly, at right angles to the usual single-line wound left by the operation. The patient passed through the ordeal moderately well. The pulse afterwards was very weak, and he hung between life and death for several days, but finally made a good recovery, thanks to the skilful management of the after-treatment by Dr. Kemp and the gentlemen mentioned, and the kind care of his friends.

Remarks.—This case, at first sight, was certainly a very unpromising one, and I publish it to add it to the statistics of shoulder-joint amputations, and as illustrating what to me has always appeared a fact,—that shoulder-joint amputations are among the most successful, in their final termination, in surgery; and now, when I have occasion to watch the progress of such cases, I always feel highly assured that "le bon temps viendra."

SILK LIGATURES REMAINING UNUSUALLY LONG AFTER AMPUTATIONS.

Some time since, I had occasion to amputate a forearm for gunshot wound. I applied four ligatures. Those on the radial and ulnar arteries remained six months. After some time they became deteriorated and broke off on pulling them. Little abscesses formed, and in about six weeks the knots came away, and left a good stump.

Again, I amputated a boy's leg at the knee-joint, and the main ligature acted in the same way, but came away at the end of three months, and the stump was an admirable one. I suppose the ligatures must have embraced some tendinous substance, together with the artery; and such cases should teach one to be, as I thought I was, careful in applying ligatures.

TRACHEOTOMY FOR SUPPOSED FOREIGN BODY IN THE TRACHEA.

Some time since, a woman came hurriedly into my office with a little girl, about 18 months old, in the last gasps of suffocation, telling me the child had swallowed a groundnut kernel the "wrong way." I immediately opened the trachea in the usual manner, the attempts at respiration being so feeble as to impede me but little. I could find nothing above or below, as far as I could go. All my attempts at artificial respiration, etc., proved ineffectual, the child having died by the time I got the trachea opened. I suppose the nut-kernel slipped into one of the bronchi as the parts became relaxed by death, having been tight enough before to produce suffocation. I could not obtain a post-mortem.

CAUTION AGAINST THE USE OF ETHER NEAR FIRE OR LIGHT.

Some time since, in removing a tumor from a woman's neck, I had occasion to use the actual cautery, and whilst doing so the ether on the towel took fire, and disconcerted for a moment all present, but did no damage except very slightly burning the patient's face. Fortunately, the bottle did not come in contact with the flame. I remember almost serious trouble to have arisen from this accident in this very way in the clinic of a distinguished surgeon. I mention it in order that it may serve its part in this important matter, and keep all on their guard when using ether near fire or light.

[The light should always be *above* the ether, the vapor of which is heavier than air and always falls.—ED. P. M. T.]

SACCHARATED CALOMEL.

BY C. G. POLK, M.D.,

Philadelphia.

IN this age, so fruitful in the invention of means for "killing bodies and saving souls," as Byron tells us, it is useless to be surprised at any innovation that may be brought forward; some of these, however, are supremely ridiculous, and among these is saccharated calomel,—the last new sensation. The uninitiated would infer from our journals that its discovery will materially enlarge the domain of medicine, and prove a panacea for all the ills to which flesh is heir.

About eight years ago, while on duty with the Seventh U. S. Infantry, I had some calomel and sugar rubbed together to facilitate its administration. About a month afterwards my hospital steward administered ten grains of this calomel to a soldier. Burning and intense pain in the stomach, with considerable nausea, followed. I administered albumen,

with an emetic, and relieved the poor fellow. On testing the saccharated calomel, I found it contained both calomel and corrosive sublimate. If any one wishes to test this, let him mix the sugar and calomel, let it stand a month or more, mix with water, pour off the water, and add a little milk of lime to it, and the yellow tinge will become obvious, showing the presence of the bichloride. In the case referred to I tested the unmixed calomel, and found it entirely free from the presence of corrosive sublimate. The *Chemical News*, November 1, 1872, says, "G. Vulpius has been examining this subject, and finds that when calomel is mixed in powder with white sugar, or calcined magnesia, or hydrated carbonate of magnesia, or bicarbonate of soda, corrosive sublimate is formed in twenty-four hours. Rather large quantities are formed in powders composed of calomel, white sugar, and bicarbonate of soda."

AN IMPROVED TROCAR.

BY THOMAS G. MORTON, M.D.,

Surgeon to the Pennsylvania Hospital.

IN performing ordinary tapping operations, it frequently occurred to me that the silver canula of the common trocar might be improved by having at its upper extremity a short additional silver tube, upon which rubber tubing of any length could be attached. Mr. Kolbe made for me, nearly a year ago, the instrument shown in the adjoining cut, which I have, with others, used with great

satisfaction. After the trocar has been withdrawn, the metal plug, which is attached to the chain, is introduced into and accurately closes the end of the canula; the fluid is thus directed through the shorter tube, and conveyed away by rubber tubing.

In hydroceles, ovarian and abdominal dropsies, this addition to the common trocar has been found very satisfactory, especially in those cases where the

patient cannot be placed in the usual position for tapping, while the bed and surroundings of the patient, so liable to be soiled in using the ordinary trocar, can be with this instrument entirely protected during the removal of the fluid.

NOTES OF HOSPITAL PRACTICE.

BELLEVUE HOSPITAL, NEW YORK.

Reported by F. W. CHAPIN, M.D.

A CASE OF STRANGULATED HERNIA.

A. S.; 47; male; U.S.; carman; admitted August 18, 1873. Patient has always been healthy, and moderately temperate. Four years ago he became aware of the existence of a hernia on the left side. The tumor was of about the size of a walnut, but has since increased to the size of an orange.

About 6 P.M. yesterday he broke his truss, but continued to work, lifting heavy iron rods. The hernia came down, and increased very rapidly in size. He attempted to reduce it himself several times. During the night he occasionally experienced slight pains in the abdomen, but did not vomit.

This morning a physician tried in vain for half an hour to reduce the hernia.

On admission, 1.30 P.M., he states that he has eaten almost nothing since last night; that since morning he has had some nausea, with increased abdominal pain; that he has not vomited, and that his bowels have not been moved for two days. His general condition on admission is good; pulse 80, regular and full. Tumor measures $13\frac{1}{2}$ inches from the peno-scrotal junction to the internal ring, and $12\frac{1}{2}$ inches transversely at its broadest part. He was put in bed; foot of bed elevated; ice placed over the tumor. This treatment was continued till 3.30 P.M., when the tumor was aspirated, once at the lower part, and again in the middle. No fluid was obtained. At 3.40, and again at 5 P.M., taxis was tried unsuccessfully. The patient was then etherized, and an incision made over the middle of the tumor from the point opposite the internal abdominal ring to the peno-scrotal junction. The layers were carefully divided on a director until a gush of a considerable quantity of sanguinolent serum indicated the opening of the sac, which was then slit up. A layer of omentum was exposed, of dark color, thickened, and exhibiting on its surface numerous turgid veins. This being laid back, a loop of intestine, nine or ten inches in length, was seen; normal in color, odor, and feel. Just beneath the intestine was a recent clot of blood, of about the size of a small hen's-egg. The constriction was found at the external ring, and divided. The internal ring was large, and had been dragged down so that the two were nearly opposite each other. Adhesions were discovered between the under surface of the intestine and the hernial sac, preventing the reduction of the former. These were divided, partly with the knife, and partly by tearing. Several small vessels which bled quite freely were closed by torsion, and one was tied with silver wire, the ends being cut short, and the remainder subsequently returned into the cavity of the abdomen with the gut. The omentum was tied with five silk ligatures, and the hernial portion then cut off. This portion was as large as an ordinary man's hand. The ligatures being firmly held, the omental stump was allowed to pass back into the abdominal cavity, and after further manipulation the intestine was also returned. The ligatures were brought out at the upper

end of the wound, and the latter, after excision of a portion of the sac, was closed with wire sutures. A compress of lint was then firmly bandaged over the inguinal canal. The operation had lasted about an hour. Pulse at the close was 96, regular, and somewhat compressible. Respiration 20; temperature 99° .

9 P.M.—Patient rallied well from the ether; is now quiet and comfortable. Has very little pain in the region of the wound; none elsewhere. Was given hypodermic of Magendie $\mathbb{M}x$ at 7 P.M., and another at 8.30 P.M.; pulse 88, respiration 16, temperature 100° .

August 11.—Pulse 88, respiration 16, temperature 100° . Patient had $\mathbb{M}x$ of Magendie again at 12 M. last night, after which he slept well. This morning he says he feels well; has slight pain across the abdomen; no tenderness. Tongue slightly coated. Pupils contracted. He has not vomited since the operation.

10 P.M.—Patient has vomited two or three times after taking food. He has been kept under the influence of opium all the time. Pulse 120, respiration 16, temperature 102° . Slight pain and tenderness in abdomen, with marked tympanites.

August 12, 9 A.M.—Pulse 98, respiration 18, temperature 100° . Patient vomits a good deal; the vomited matter is bitter. Ordered

R Acid. hydrocyan. dil.,
Spts. chloroformi, $\mathbb{a}\mathbb{a}$ $\mathbb{M}xvj$;
Aq. calcis, $\mathbb{z}ij$.—M.

Sig.— $\mathbb{z}i$ q. 2 h.

5 P.M.—Pulse 84, respiration 26, temperature $100\frac{1}{2}^{\circ}$. Some tympanites and tenderness. No vomiting since morning. Patient continues to take morphine quite freely. Nourishment is given frequently in liquid form.

August 13, 8 A.M.—Pulse 84, respiration 16, temperature $100\frac{1}{2}^{\circ}$. Patient feels well; no pain; slight tenderness and tympanites of abdomen; no vomiting. Takes nourishment readily,—beef-tea and egg-nog, $\mathbb{z}ii$ q. 2 h., alternating. Dressings removed from wound. Scrotum but little swollen. Union exists in wound except at upper part, where the ligatures protrude, and about an inch at the lowest part. There is slight suppuration at each of these points. Pad over inguinal canal reapplied; scrotum supported by a band of adhesive plaster passing under it from one thigh to the other. Treatment by morphine and liquids continued.

7.30 P.M.—Pulse 92, respiration 18, temperature 102° . Patient has delusions; answers questions rationally.

August 14, 9 A.M.—Pulse 86, respiration 20, temperature $98\frac{3}{4}^{\circ}$. Delusions continue; patient feels well; no pain; no vomiting; some abdominal tympanites; some tenderness at lower part of abdomen, most marked on the left side on deep pressure. Scrotum slightly swollen and oedematous. Stitches removed from wound; union throughout, except where the ligatures protrude. No pus collected in scrotum. Morphine and liquid food continued.

4 P.M.—Pulse 86, respiration 20, temperature $99\frac{1}{2}^{\circ}$. Delusions and hallucinations continue; patient gets out of bed unless watched closely.

August 15, 9 A.M.—Pulse 88, respiration 22, temperature $98\frac{1}{2}^{\circ}$. 5 P.M.—Pulse 96, respiration 28, temperature $99\frac{1}{2}^{\circ}$.

Patient is delirious; is sweating profusely; has marked muscular tremor. Friends state that he had been drinking hard for a long time previous to admission.

August 16, 9 A.M.—Pulse 112, respiration 30, temperature $100\frac{3}{4}^{\circ}$. Patient still delirious; constantly talking and struggling. Tongue dry and coated brown; teeth covered with sordes. He complains of thirst. Wound looks well; swelling of scrotum diminished. Patient had a copious discharge from the bowels this morning. No abdominal pain. Very little tympanites. No ten-

derness except near the wound. Ordered nourishment to be continued as usual, with \mathfrak{z} ss of brandy q. 2 h.

5 P.M.—Pulse 100, respiration 24, temperature $100\frac{1}{2}^{\circ}$. Patient had another passage from the bowels; is still delirious. Ordered pot. brom., gr. lx; cum chloral hydrat., gr. xx; to be repeated in four hours if sleep should not ensue.

August 17, 9 A.M.—Pulse 100, respiration 24, temperature $99\frac{1}{2}^{\circ}$. Bromide and chloral were given at 7 and 11 P.M., yesterday, and patient slept well all night. P.M.—Pulse 88, respiration 26, temperature $99\frac{1}{2}^{\circ}$.

Patient has been quiet, though slightly delirious, all day; has no abdominal pain or tympanites; is allowed to take solid food.

August 18, 9 A.M.—Patient is quiet and more rational; slept well all night. Tongue moist and thinly coated. Bowels moved last night. Slight suppuration at the point of exit of the ligatures; elsewhere union is firm. From this time the patient progressed satisfactorily.

The first omental ligature came away on August 29, and the last one was removed on September 10. On October 10 the patient was discharged and told to wear a truss, although there were no signs of a hernia.

This case presented some instructive features. The hernia was a large one, the sac containing both intestine and omentum,—a large piece of each. It was the omentum which suffered chiefly from the strangulation. And this was a fortunate circumstance; for, had the intestine suffered equally, the case would certainly have been a hopeless one. A large piece of omentum covered the gut, forming a sort of cushion for it at the seat of constriction, and thus preventing its complete strangulation by the firm, sharp, and unyielding boundaries of the external ring, until surgical interference gave relief. The omentum was found to be on the verge of sloughing. The intestine beneath it was "normal in color, odor, and feel."

Had the space occupied by the omentum been filled by intestine, it is plain that some portion of the latter would have suffered as the omentum did. The prognosis, as it was, however, was necessarily doubtful; for it was almost impossible to do no harm to the intestine while tearing and cutting it away from the sac, to which it was bound by firm adhesions. And again, the returning of so large a stump of omentum ligated in five sections, each ligature embracing a considerable amount of tissue, was a doubtful, though unavoidable, experiment. It was a month before the omental ligatures had all come away.

In spite of the drawbacks already mentioned, and of a severe attack of delirium tremens, the patient, *whose gut had been but little injured*, made a most satisfactory recovery.

THERAPEUTIC NOTES.

NEW MODE OF ADMINISTERING IODINE.—A combination of iodine with some organic substance of such a nature as to allow, by its decomposition in the economy, the liberation of this element, has long been a desideratum.

Such a combination M. Collas thinks he has found in iodized albumen, which combines ease of administration with certainty in composition. The presence of iodine in this compound cannot be distinguished until after the destruction of the organic matter. Iodized albumen is prepared by shaking briskly together a solution of albumen with iodine, in very fine powder, or in solution in an appropriate vehicle. The mixture, at first dark brown, becomes decolorized after some hours of contact, and no longer gives a violet color with

starch. The product is then dried at a gentle heat and made into pill form, divided in such a manner that each pill shall contain three-fourths of a grain of iodine.

DIGITALIS IN PUERPERAL CASES.—Dr. Winkel, who has made various experiments with the different preparations of digitalis, does not hold it to be a specific in puerperal fever, but administers it as a prophylactic against the phlegmonous process. Where disturbance of the digestion results, he discontinues its use. Dr. W. found the hypodermic use of digitalin dissolved in equal parts of alcohol and water, in the proportion of .001 gramme of digitalin in 3 grammes of fluid, to be the best method of administration. The mean requisite dose is .005 gramme. The advantage of this preparation is found in the smallness of the dose and the ease with which its action may be regulated. The effect follows in one to three days generally, a simultaneous sinking of temperature and pulse being observable. Elimination cannot be absolutely stated to take place through any organ. Digitalin appears to act upon the brain, producing rest, better sleep, and enlargement of the pupil. It appears also to act as a styptic, recommending itself in this respect after severe hemorrhage.

The question as to the tolerance by puerperal women of large doses cannot as yet be answered, the assertion of its only partial absorption through the altered condition of the intestine being unsupported by proof. The favorable action of digitalis is attributed by Dr. W. to its effect upon the circulation; for, as in the chills of the puerperal condition the prognosis is more favorable when the pulse is not over 100, it is evident that a remedy which will prevent such increase must be beneficial. The observation of after-pains following the continued use of digitalis, together with its styptic action, has given rise to the conjecture that its effect is upon the unstripped muscular fibres of the uterus. By its contraction of the capillaries it prevents exudation of the colorless blood-corpuscles.

PICRATE OF AMMONIA IN INTERMITTENT FEVERS.—Dr. Beaumetz, who some time previously had urged the use of this remedy before the Société de Thérapeutique, again mentioned at a recent meeting the success which he had attained by its administration in the treatment of rebellious intermittents after the entire failure of sulphate of quinine. In his hands it had failed but once, while its success in many other instances was remarkable. Two-thirds of a grain daily is said to be sufficient.

JABORANDI—A NEW SUDORIFIC AND SIALAGOGUE.—Dr. Coutinho, of Pernambuco, has introduced to the notice of the profession a plant hitherto known only in Brazil. According to the testimony of Dr. Rabuteau, this plant possesses the most decided diaphoretic qualities, and, in addition, acts as a powerful sialagogue. An infusion of fifty grains of the powdered leaf in about six ounces of water, although partaken of when cold, produced within three-quarters of an hour profuse sweating, accompanied by free salivation.

M. JACQUES DE MAY, a Parisian pharmacist, has devised an ingenious method of applying various ointments with accuracy to such semi-cavities as the conjunctiva, etc. The ointment, which should be mixed with twenty per cent. of oil to insure fluidity, is simply placed in a flexible tube of tin, such as is used by painters for moist colors. By this means it is kept from contact with the air, and may be squeezed out in a vermicular cylinder and directed accurately and in measured quantity just where it is wanted.

HYPODERMIC USE OF ERGOTIN.—M. Drasche, Rudolf Hospital, Vienna, uses the following hypodermically: ergotin, five grains, in a fluidrachm of glycerin; dose, twelve minims.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY
J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 30, 1874.

EDITORIAL.

THE AMERICAN MEDICAL ASSOCIATION.

AS our readers are aware, in a very short time the American Medical Association meets. Already have editorial quills been busy with the coming event, and the annual rain upon the much-abused Association has set in. The most unkindest cut of all is, to our thinking, a recent editorial in one of our New York cotemporaries, in which the virtuous, though sleepy, critic upbraids the Association for not doing last year that which it did do, and acutely argues for the adoption at the next session of certain organic laws, which were really acted on and passed at the St. Louis meeting. We are rejoiced to find that Philadelphia does not have a monopoly of Rip Van Winkles, and to learn that the whirling metropolitan maelstrom has one corner in which it is possible to enjoy a year's nap.

The journal referred to advises most strongly that a committee be appointed to consider ethical questions. In truth, such a committee was chosen, under the name of "Council," and, as any one can see by looking over the printed Transactions, has met and entered upon the revision of the Code of Ethics.

The relief afforded by this Council, we believe, will be very great. The bad repute of the Association is very largely due to the disputes to which questions of ethics have given rise; indeed, the ethical disorder has been so violent as to threaten dissolution. We trust the remedy will be found sufficient, and that the waste of time in unseemly quarrels will occur no more. This much accom-

plished, does anything more remain to be done, and is it possible to have an association which shall represent the profession of the United States as the British Association does that of Great Britain? Answering the last of these questions first, we are inclined to say "No."

There are certain geographical or physical laws which it seems to us must prevent our Association from attaining the position held by the English body; chief among these is the great extent of the country. In England, let the Association meet almost anywhere, the bulk of the practitioners in the kingdom can go to it by some early morning train, and return the same night; but here, to attend the meetings is a work of days, and sometimes of weeks, and the expense is commensurate with the time consumed. As the Association usually gathers in a fairly busy month, it is unreasonable to expect a large proportion of the most active practitioners to attend its sessions. If the meetings were arranged for August, and were held in some cool northern position, it is possible the attendance would be more representative of the best and busiest section of the profession.

The great size of our country also lessens the attractiveness of our Association to individuals. Sir William this or that goes to the British Medical because he meets those who either call him in consultation, or who he hopes will do so; for all England is his field of practice. Leading practitioners here may find it their interest to attend State medical conventions; but who expects to be sent for in consultation one or two thousand miles? Evidently, the most powerful of motives—self-interest—draws the professional leaders much more strongly in England than it does with us.

Be these things as they may, we are of those who believe in the necessity of some central organization, which shall, as far as possible, represent the profession in the United States, and we intend, therefore, to sustain the American Medical Association as much as we are able. Free discussion is the only way to arrive at the truth, and it behooves every medical man to ask himself, what can be done to build up the central society? The ethical troubles having been settled, the next point evidently is to get as high a class of delegates as possible. To secure this, a motion was offered at the last session, and is to be acted upon at the Detroit meeting, confining representation to such County and District Medical Societies as are recognized by their respective State organizations, and to the army and navy. The chief object of the resolution is to cut off the colleges; and we think this is a good move; yet it appears

that it would be better to allow representation of such educational institutions as really require a three years' course of study. The only school in the country that could claim a position would be Harvard, and the by-law would be a standing protest against the present educational Cheap John system so degrading to the profession. The proposed by-law certainly needs some alteration in language, if, as appears to us, it cuts off such medical bodies as our College of Physicians and the New York Academy of Medicine, to say nothing of pathological and other lesser societies. In Philadelphia a very large proportion of the best men of the profession belong to the College and do not belong to the County Medical Society; so that, as far as concerns this city, the proposed amendment would be simply suicidal.

A matter upon which no action has been taken, that we are aware of, is the Transactions. Of these, twenty-four volumes have been published; and on referring to vol. xxiii. we find the expense for that year was fourteen hundred dollars. Estimating the annual outgo as one thousand, we get a total of twenty-four thousand dollars; spent in what? Simply in disgracing the American profession before the world. A grain of wheat here and there, to be sure, but mainly chaff, chaff, chaff, fit only to be burnt up by unquenchable fire. Let us do away with the Publication Committee altogether—put an end to that body, whose organic type does not rise as high as that of the amphioxus, the lowest of the vertebrata, in that it is not even furnished with a *chorda dorsalis*. The Association may rely upon it that anything worthy of preservation occurring at its sessions will be embalmed by the journals, and that it would be a general relief if the Transactions were confined to the business minutes. A thousand dollars a year, properly expended, would be a godsend to American medical science. What we most need is original investigations. Let two prizes of five hundred dollars each be offered, and *not given unless earned*, and we conceive the result would be most happy. In a recent article upon "Universities: Actual and Ideal," Prof. Huxley says,—

"The other day an emphatic friend of mine committed himself to the opinion that, in England, it is better for a man's worldly prospects to be a drunkard than to be smitten with the divine dipsomania of the original investigator. I am inclined to think he was not far wrong. And be it observed that the question is not whether such a man will be able to make as much out of his abilities as his brother, of like ability, who goes into law, or engineering, or commerce; it is not a question of 'maintaining a due number of saddle-

horses,' as George Eliot somewhere puts it; it is a question of living or starving."

What is true of England is a hundred times more true of America. With as much of talent, we firmly believe, as any other country in the world, we do not accomplish as much of original investigation as a third-rate German town; largely because we systematically starve out, or indifferently freeze with neglect, such talent. To be sure, our lordly association offers the magnificent sum of one hundred dollars as a prize. No wonder it gets prize essays which the medical journals would scarcely print.

We acknowledge that five hundred dollars is too small a sum for the Association to offer as an inducement to original investigation; but let us not despise the day of small things, and as it is probable that at first the country could not produce more than one essay worthy of the prize, a fund might be obtained for increasing the amount.

CORRESPONDENCE.

SLOWTOWN, May 15, 1874.

SIR,—I have read with indignation which I do not care to conceal the recent shameless attack upon the Board of Trustees in this city. Exhausted by the cares and trials of the recent election to which your correspondent alluded, I fled to a distant watering-place to recruit my conscience and my shattered constitution, and there in a reckless morning journal I read the cruel and covert attack upon the body to which I am proud to say I belong.

It is impossible to leave unanswered the charges thus made, and when I assure you that in no instance did more than one hundred and thirty-two persons call upon me for any single candidate, that the board in question contains no grandmothers, that your definition of canvass exists in no dictionary, that the cost of our broken-door bills is provided for by a fund left to the college ages ago by a successful candidate, I trust you will be satisfied.

Perhaps you would like to know how we do really secure a good choice. In the first place, we ascertain who among the candidates lectures best. This we get at by asking their office-students. If a man lectures well, we drop him at once, since it is our policy to train our own professors, and what would be the use of training a man who can already lecture? If, too, we find out that a man has written essays which are valued and quoted in Europe, we put him aside, because it is impossible that any one abroad can know as much about a doctor as we do. In this way we manage to eliminate until we have left some one who having a minimum of past reputation will be sure to work hard in order to acquire a future name. In other words, we go in for expectation. We thus make sure

that our professors shall be active working men, with a reputation to make, not an effete people who have worn out their brains in past efforts. Our men are to be taken on trust; and this is the real meaning of the word, —a trustee being a fellow who elects a fellow whose future is to be taken on trust by other fellows in general.

Yours, etc.,

AN INDIGNANT TRUSTEE.

PHILADELPHIA, May 10, 1874.

DEAR SIR,—Many years ago I had the grim misfortune to become a candidate for a vacant chair in this city, and I beg to assure you that the fun of *Lancet's* letter from Slowtown but faintly describes the reality. Consultations of my friends were held as to every trustee—twenty-four, I think. Who were their clergymen, doctors, creditors, relatives? What church influence reached them? Which of them were believed to listen to advice from their wives, and who were their wives' clergymen? and so on. Who was to be pushed steadily? who not? Who needed somebody else "on him"? I assure you, sir, I look back with loathing on that time; and yet no man who has tried this vile path to preferment can say I overdraw the picture. Some one may answer, Why do physicians resort to such devices? Why not send to the individual trustees a list of the papers you have written, invite them to hear you lecture, or give them the written opinion of half a dozen men of note as M.D.'s concerning capacity to teach? Ask them to write, as they should do, to the dozen or so of men in your own line throughout the country who can say with authority of what force you are in the pursuit you profess to have excelled in, and then leave to them the freedom of a thus instructed choice.

Does any man who reads this presume that such a course would prevail against the grandmothers, church influence, insurance-board associations, this or that railroad? I for my part see no hope save one. The time will come here, as it has come in New York, when the faculties will possess the true power to elect, or at least to nominate; when they will have representation in boards of trustees, and when the alumni will insist upon a like privilege; then may we expect to see mercantile and other considerations which are called "influence" yielding to an honest judging of the candidates by the mode in which they have illustrated their branch, and by the known measure of their capacity to excite their own enthusiasm for its pursuit in those whom they teach.

Faculty representation.

Alumni representation.

These are what we want in our boards of trustees.

My remarks are called out by unwholesome memories of a past canvass, in which I did not get off with triumph, nor has what I have urged been meant to have the least reference to any contest which has taken place of late. The concours and the German system of promotion have alike their faults, but in the con-

cours it is at least impossible for the worst man to be chosen, while under the German plan he who does not justify his elevation to a lower class of chairs is little likely to rise to a higher one. Work of some kind—original productiveness—is there the test, and is, in fact, a good, if not a perfect one.

Yours,

MAT. MED.

PROCEEDINGS OF SOCIETIES.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

MAY 4, 1874.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

DR. JAMES TYSON exhibited a beautiful case of one hundred microscopical specimens in pathological anatomy, prepared by Dr. Otto Barth, of Leipsic, which he had recently purchased. He remarked that while he had found some of the sections so thick as to be almost worthless, the majority were thin enough to display structure quite satisfactorily with moderate powers such as 200 diameters. The preparations comprised illustrations of a great variety of diseased organs, and among the rest he would call particular attention to those illustrating the pathology of croupous and catarrhal pneumonia, tubercle, and the different forms of renal disease, including the fatty kidney, the granular kidney, interstitial nephritis, and the lardaceous or amyloid kidney, showing casts, apparently of the lardaceous material, blocking up the tubules. This latter example was important on account of its bearing upon the question as to whether lardaceous disease could be diagnosed by the appearance of casts, which he considered quite possible in some instances, although he had himself never been able to obtain the red reaction of iodine in so-called waxy casts, as found in the urine.

Dr. JOSEPH G. RICHARDSON remarked that he had likewise experimented very often upon the reaction of iodine with the tube-casts of amyloid disease of the kidney, and had in three separate cases been able to obtain the characteristic mahogany-red tint with iodine, acting upon the wax-like casts. In two of these cases he had made the diagnosis of amyloid form of nephritic disorder in patients in the Pennsylvania Hospital, and had the correctness of the opinion fully confirmed by subsequent post-mortem examination. In a recent instance he had been fortunate enough to meet with a small waxy cast, enclosed in a larger one of the ordinary pale, granular variety, and found it, of course, an excellent opportunity for demonstrating the dark-red tint of the iodized amyloid material, as contrasted with that pale-yellow hue given to most animal matters by tincture of iodine, and which Dr. Grainger Stewart states he has never seen exceeded in tube-casts.

Dr. TYSON said he had demonstrated to his satisfaction the futility of testing this reaction with alcoholic solution of iodine, which produced a granular precipitate of albumen throughout the fluid, and completely obscured the field of view.

Dr. RICHARDSON desired to correct his statement by adding that he used in these experiments not the tincture of iodine (mentioned inadvertently), but a diluted solution of the liq. iodini comp., U. S. P.

Dr. J. GIBBONS HUNT inquired how these preparations of Dr. Barth were hardened for cutting the sections.

Dr. TYSON said that he had no definite information respecting these particular specimens, but thought from what he knew of German methods of work that they were probably hardened for cutting in solution of bichromate of potassium or of chromic acid. From an accident which had occurred to one of the preparations, resulting in the fracture of its thin glass cover, he was led to conclude that they were cleared with oil of cloves and mounted in balsam.

Dr. HUNT remarked that when he had first seen the preparations of Dr. Barth, he thought they were reasonably respectable; but on closer examination he had found the cellular elements of the structures shrunken and altered, until, like too many of our own mounted specimens, they came to look merely like caricatures of the tissues, from which they were actually prepared by a process of distortion. All the productions of Dr. Barth which he had carefully inspected were, he believed, hardened in alcohol, by the imperfect method now used in the Army Medical Museum at Washington. According to his own experiments, structures which have been judiciously hardened in chromic acid solutions, and properly stained, especially with hæmatoxylin, exhibited all their cell-elements with admirable distinctness. So superior were the chromic acid solutions, that he could easily demonstrate in a portion of spinal cord, suitably hardened in Müller's fluid, not only every minute blood-vessel, but even the red blood-corpuscles which they enclosed. In proof of these statements he had brought with him to the meeting a section of kidney hardened as above suggested, and stained with perchloride of tin, which exhibited the cells lining the convoluted tubules, the straight tubules of Henle, and even the delicate cell-layer seated upon the inside of the capsule of the Malpighian bodies, as he had never before seen it demonstrated.

Dr. TYSON quite agreed with Dr. Hunt in his unfavorable estimate of alcohol as a menstruum for hardening tissues, and had, some time since, concluded to abandon its use for that purpose. He wished to know whether Dr. Hunt had not been able to bring into view the endothelium of Bowman's capsule by means of nitrate of silver.

Dr. HUNT replied that the silver method enabled us to demonstrate these cells without much difficulty, but at the same time less satisfactorily than the one he had proposed. If delicate cell-elements are properly stained they can be with ease perfectly preserved in balsam, whilst it is only by superior skill in manipulation that thin sections can be prepared and mounted permanently in glycerin.

Dr. TYSON remarked that when in London, two years since, he had had an opportunity of examining some of the glycerin-preparations of Dr. Lionel Beale, and found them just as figured in his various works. They were not, however, sections, and he could not understand how sections could be made of preparations which had only been treated with glycerin, because in it there is no hardening power, and no chance is afforded for the production of any but teased-out specimens. He desired to ask Dr. Hunt what his experience had been in the preparation of specimens by freezing.

Dr. HUNT replied that the method by freezing did not involve any more trouble, but had the disadvantage of requiring special and, for its most successful practice, somewhat complicated apparatus. He considered it very important that the action of the frigorific mixture should be stopped short at the point of waxy hardening, and not allowed to proceed until the stage of completely brittle congelation is reached.

Dr. RICHARDSON exhibited a specimen of leucocythæmic blood preserved in a perfectly sweet condition by mixture with an equal bulk of hydrate of chloral

solution (3j to fʒi), and mentioned as a peculiarity of the case of leucocythæmia the rapidity of increase of the white blood-corpuscles, their ratio to the red disks being as 1 to 2 ten days before the patient's death, whilst after dissolution it was found to be as 2 to 3.

REVIEWS AND BOOK NOTICES.

TREATMENT OF NERVOUS AND RHEUMATIC AFFECTIONS BY STATIC ELECTRICITY. By Dr. A. ARTHIUS. Translated from the French by J. H. ETHERIDGE, M.D., Professor of General Therapeutics, Rush Medical College, Chicago.

Who Dr. Arthius is we do not know, and, if we may judge from the preface of the translator, the American godfather does not appear to have any more definite idea as to the father of his adopted child, for he states that the original treatise was handed him by a friend, who received it from a friend who had been a patient of Dr. Arthius.

If any one of whose truthfulness we had not the clearest knowledge should say to us that he had cured, by a few applications of electricity, epilepsy which had lasted for twelve years, and at the same time restored a right arm that was withered and powerless, we would gaze on him "with a smile that was childlike and bland." Precisely this is what is claimed in the brochure before us; and can we be blamed that the famous witticism which tradition attributes to Dr. Rush has been uppermost in our mind?—"The French lie, and Dr. ——— relies on them."

The tone of the book seems to us to indicate that it has been written rather for the laity than the profession; rather to be handed to the seeker after health in the office, than for sale to doctors.

There are several points of interest in the book; chief among them is the so-called "fluidique bath," by which is meant placing the patient upon an insulating stool, and connecting him with the prime conductor of an electric machine; of this marvellous bath it is written that "the fluidique bath induces an acceleration of the pulse, and is singularly calmant, eases the respiration, develops animal heat, augments cutaneous transpiration, makes more active the urinary secretion, disperses nervous irritation, gives tone to the whole organism, increases the vital forces, and augments the energy of absorption," which is altogether too glibly said to induce us to believe that it was in any way proven by rigorous experimentation.

The most extraordinary statements are made by Dr. Arthius in regard to the diagnostic use of static electricity. We are told that when a person is charged by means of the electric bath, and the hand or a metallic conductor passed over the body, the moment a diseased part is reached it will at once be perceived by both patient and doctor. Hence we can search for disease as the peasant searches for water with his witch-hazel.

Other marvels are told of in this book of Aladdin's lamp; metals are said to be carried into the system by this wondrous static electricity, and the powers of medicines to be increased manifold times. The entertaining character of the book is not lessened by some ludicrous wordings, for which, it may be, we have to thank the translator. Thus, Dr. Arthius speaks to a patient of electricity generated by piles, and hence of hemorrhoidal nature, we suppose.

In taking leave of the brochure, we cannot but express a wish that what it says were true; as, were it so, new diagnostic and therapeutic powers of great value would be in our grasp.

GLEANINGS FROM OUR EXCHANGES.

SUB-CORACOID DISLOCATION OF THE SHOULDER WITH FRACTURE AND ANCHYLOSIS (*The Irish Hospital Gazette*, May 1, 1874).—At a meeting of the Dublin Pathological Society Prof. Bennett presented the right scapula and humerus, taken from a dissecting-room male subject, which presented some unique features. There was no life history. The muscles situated around the shoulder-joint were wasted, but not in a state of advanced degeneration; therefore the accident which caused the anchylosis could not have occurred very long before death. On examining for the cause of the anchylosis, a sub-coracoid dislocation of the shoulder, with a fracture of the upper part of the humerus, was detected. Of this variety of fracture, said Prof. Bennett, only eight examples were recorded by Malgaigne. An example was also recorded in Anger's *Traité Iconographique des Maladies Chirurgicales*, in which, however, the right humerus was depicted with the left scapula; this specimen might consequently be legitimately excluded as being a made-up case. The fracture in these instances passed through the anatomical neck of the bone, then through the bicipital groove, and involved two or three inches of the shaft of the humerus. It is an oblique fracture, and generally spares the great tuberosity. In the present specimen the tendon of the biceps was included in the callus of union. Prof. Bennett observed that his case was unique, as he was not aware of any other of this form of dislocation and fracture of the humerus that had been followed by anchylosis.

SIMULATED DISEASE (*The Lancet*, April 4, 1874).—Messrs. Davidson and Puzey report a case of feigned hemiplegia, and conclude that, in investigating the symptoms of motor paralysis, the following tests are available:

1. The well-known appearance of dragging in a paralyzed leg; 2, the test suggested by Dr. Hughlings Jackson:—in real hemiplegia the paralyzed arm falls forward when the patient stoops; in a case of feigning, the arm will probably be retained by the side; 3, the condition of the muscles in long-continued paralysis:—where paralysis has continued for several months in a limb, we should expect that the muscles would both diminish in size and lose their electro-contraction; 4, in cases where the patient says that he has been confined to bed for many weeks, the condition of the soles of his feet may be taken as a test of the correctness of this statement. A scaly and cracked condition of the cuticle of the soles will, according to our experience, be invariably found in adults (at least in the lower ranks of life) who have been confined to bed for a considerable time.

In all cases of suspected feigning of disease we should endeavor to ascertain whether the patient has had opportunities of becoming acquainted with the symptoms of the disease supposed to be simulated.

ELEPHANTIASIS GRÆCORUM.—Dr. Leisrink relates a case of this kind in the *Deutsche Zeit.*, vol. iv., in which he tied the femoral artery just below Poupart's ligament. The lady, 51 years old, had suffered twenty-five years before from repeated attacks of erysipelas in the right leg, and the latter measured twenty inches round the calf, whilst the sound leg measured only seven. She was considerably weakened by oozing of serum, and four days after the operation the size was reduced to twelve inches. It rose a little afterwards, and, although the patient was not actually cured, the disease was certainly arrested and modified. Compression of the artery has been tried in this and other countries with varying success, but amputation has almost always proved fatal.—*London Lancet*.

ACUTE SOFTENING OF SPINAL CORD (*The Lancet*, March 28, 1874).—A girl, æt. 11, who had always enjoyed perfect health, was seized with shiverings and pain in the limbs, and, four days later, suddenly lost the use of her legs. Paralysis of motion was complete; sensation was diminished in the right leg, and was absent in the left. There was no reflex action. The condition grew worse; the arms became involved, and at the end of a week she died. At the post-mortem examination a quantity of serous fluid was found in the spinal arachnoid sac, and the cervical portion of the cord was soft and disintegrated.

GUNSHOT WOUND OF HEART (*Indian Medical Gazette*, 1874).—A tiger was shot with a rifle from a distance of about four feet. He ran a distance of about one hundred and forty feet, and then died. It was found that the ball had struck him about an inch to the right of the spine, passed through the right lung, struck the heart in the septum ventriculare, below the right auricle, and torn a huge hole through the right ventricle, besides opening the left into the right. It had then grazed the left lung and emerged below, an inch and a half to the left of the mesial line.

SUDDEN DEATH AFTER WOUND OF A FINGER (*Gazette des Hôpitaux—Clinic*, March 7, 1874).—A man was wounded at the extremity of an ungual phalanx by a hatchet. The wound was dressed by a simple bandage. Progress was favorable. The wound began to cicatrize, with very little suppuration. There was no fever, or even malaise, and the patient was soon able to work about the hospital. Suddenly, as he rose from his bed one day, he fell to the floor dead. A careful autopsy revealed evidence of intense bronchitis, and eight or ten abscesses in the liver.

TREATMENT OF TÆNIA (*The Medical Press and Circular*, March 25, 1874).—Dr. Bill recommends the use of phenic acid in the treatment of this worm, and gives an illustrated case where koussou, male fern, turpentine, and other remedies were useless. He gave six grains of phenic acid in half a pint of water four times a day; in two days segments of the worm were discharged. He then gave the acid in shape of pill, and on the third day the remainder and head of the animal were discharged.

TREATMENT OF ALCOHOLISM BY NUX VOMICA (*Irish Hospital Gazette*, May 1, 1874).—Dr. Luton has obtained excellent effects from the use of nux vomica in chronic alcoholism where the evil has not passed into the absolutely degenerative stage of tissue-change. In the tremors, cerebral, gastro-intestinal, and thoracic disorders of alcoholism, he resorts with confidence to the use of extract or tincture of nux vomica in ordinary doses.

TREATMENT OF VARICOSE VEINS (*Dublin Journal of Medical Science*).—"Should the surgeon be urged to meddle with varices, we would suggest, in preference to the use of the Vienna paste, a careful injection of the vein with the perchloride or the subsulphate of iron. More people have probably escaped death from this treatment than from any of the other numerous operative measures invented for the treatment of the varicose condition of veins."

CONGENITAL STRANGULATED HERNIA IN AN INFANT.—Dr. Somerville (*British Medical Journal*, January 3, 1874) reports the case of a child ten days old, who suffered from a congenital strangulated hernia. A spontaneous cure took place.

A USEFUL extemporaneous splint for fractured limbs is suggested by M. Noiset, consisting simply of gutter-shaped pieces of zinc or tin plate, perforated if possible, for the sake of reducing its weight.

MISCELLANY.

HYDROPHOBIA.—The police authorities in Vienna call attention to the fact that numerous cases of hydrophobia have recently occurred, and that many persons have been bitten by dogs which were actually mad or supposed to be, and have also issued circulars of advice to the owners of dogs. They say that the possessors of these animals should take good care of them, and watch attentively for any symptoms of disease which may indicate the beginning of rabies. Unusual irritability and loss of appetite are set down as sufficient to cause anxiety, even when the animal still continues to drink water. Dogs presenting these symptoms are to be secluded and watched, or, with due precautions, handed over to the authorities of the Imperial Institution for the Care of Diseased Brutes. Dogs are not to be taken into public conveyances or brought into hotels, coffee-houses, and like places of public resort, and when they are taken upon the street, a leash must be used. Violation of these rules subjects the animals to the risk of capture and death from the officials charged with this duty.

It is generally imagined by the public that the antipathy of the profession to quackery originates in a feeling of self-interest, and that quacks take the bread from medical men. We more than doubt if this is true. If the faculty lose and quackery gains a particular case, that is amply compensated by the ill health which quackery produces in thousands, and the disposition to fly to physic which it generates in millions. On the whole, the profession probably gains by quackery—certainly its loss must be very trivial. A feeling of self-interest can sway the profession very little either way, and its antipathy to quackery must be sought on other grounds.

We should say that our aversion to quackery takes its rise in a natural feeling of disgust at a barefaced system of humbug. Unless men's minds are warped by the strongest motives towards wrong, they revolt at witnessing it. We see a knot of rascals fleeing and injuring the public by the most dishonest and scandalous arts. We naturally evince contempt and indignation towards the miscreants.—*Canada Lancet*.

PROSECUTION FOR SYPHILITIC VACCINATION.—At a recent sitting of the criminal tribunal of Hamburg, a public vaccinator, Dr. S., was found guilty of causing injury to the body by neglect, through vaccinating from a syphilitic child, and was sentenced to a month's imprisonment. The facts of the case were briefly these: On August 21 of last year, a male child a year and a half old was brought to the vaccination station of which the defendant had charge, and, under the directions of the defendant, whose duty it was to choose the children from whom vaccination should be performed, was vaccinated from a child a year old, who had syphilis, and itself became affected with the disease.—*British Medical Journal*.

We are indebted to Dr. William W. Keen for an opportunity to read some letters from Dr. John C. Berry, Medical Missionary in Japan. The government has permitted the opening of a dissecting-room under the charge of Dr. Berry, and the Japanese native doctors manifest the greatest enthusiasm in studying practical anatomy. Dr. Keen's edition of Heath's Dissector's Manual is being translated into Japanese, and the proofs of copper (?) engravings made by native artists are the handsomest anatomical cuts we have ever seen.

THE number of students attending the lectures of the Vienna University during the past semester was 3813, of which number 1109 were students of medicine. In the total number, 3813, there is an increase of 373 over the number of students registered for the summer session of 1873.

A CORRESPONDENT in the *London Pharmaceutical Journal* wants to know what becomes of the enormous quantity of *Cocculus Indicus* that is imported. From his statement, it appears there are at present in stock in London some twelve thousand pounds of this poisonous drug, with no visible means for its consumption.

DR. A. E. SANSOM has been appointed Assistant-Physician to the London Hospital.

NOTES AND QUERIES.

MULTIPLE IMPREGNATION.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The article entitled "Multiple Impregnation," published in the *Philadelphia Medical Times* of the 18th ult., has recalled a similar instance. While in Arizona, I had in my possession a white slut (pointer), which was covered by a dog of her own color and species, and the next day by a black, long-haired cur. In due time she gave birth to seven white pups, and in thirty hours to another which had coarse black hair and resembled the cur in every particular. I watched the growth of these pups with great interest, and found that while the white pups learned to hunt birds intuitively, it was almost impossible to teach the black one.

Very respectfully,
BLUE PILL.

SAN FRANCISCO, CAL.

INAUGURATION OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

The inauguration of the splendid new hospital which has been erected in connection with the Medical Department of the University in West Philadelphia will take place on Thursday, June 4, at three o'clock P.M. Governor Hartranft will preside at the ceremony, and Hon. William A. Wallace will deliver an address. All medical alumni of the University are invited to attend.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 19 TO MAY 25, 1874, INCLUSIVE.

BILL, J. H., SURGEON.—Relieved from duty at David's Island, N. Y. H., and assigned to duty as Post-Surgeon at Fort Wood, N. Y. H. S. O. 94, Military Division of the Atlantic, May 9, 1874.

FRYER, B. E., SURGEON.—Relieved from duty at Fort Wood, N. Y. H., and assigned to duty at Fort Wadsworth, N. Y. H. S. O. 94, c. 8., Military Division of the Atlantic.

TILTON, H. R., ASSISTANT-SURGEON.—Assigned to duty at Fort Sully, Dakota Territory. S. O. 94, Department of Dakota, May 12, 1874.

MIDDLETON, P., ASSISTANT-SURGEON.—Assigned to duty at Fort Duncan, Texas. S. O. 72, Department of Texas, May 12, 1874.

SATURDAY, JUNE 6, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE.

OUR EYES—HOW TO TAKE CARE OF THEM.

Abstract of a Lecture delivered at the University of Pennsylvania,

BY WM. F. NORRIS, M.D.,

Clinical Professor of Ophthalmology.

Reported by S. D. RISLEY, M.D.

LECTURE II.

GENTLEMEN,—At my last lecture I called your attention to three types of eyes—the emmetropic eye, which in a state of rest is able to focus parallel rays of light upon the rods and cones of the retina; the hypermetropic eye, which we saw was too short in its antero-posterior axis, and parallel rays of light were, in consequence, intercepted before reaching their principal focus, thus giving indistinct vision; and finally, the myopic or short-sighted eye, which was too long in its antero-posterior axis, so that parallel rays, after reaching their principal focus, crossed over before reaching the retina, and objects were here again seen indistinctly. It is principally to this latter type, the myopic, that I desire to call your attention to-day.

Long ago, Professor Edward Jaeger, by careful ophthalmoscopic examinations of a considerable number of new-born children, proved that the majority are at birth slightly myopic; and his observations upon the cadaver show that this is dependent on the undue convexity of the lens, which in the foetal state having been quite globular has not yet assumed its proper form. Later it becomes less convex, so that myopia becomes emmetropia, and the already emmetropic eyes become hypermetropic.

The serious troubles attendant upon myopia, and its evident tendency to increase in degree, have led many observers to investigate minutely the causes which were active in its production and increase. Dr. Cohn, of Breslau, showed, by the examination of the eyes of over ten thousand of the school-children in that city and its vicinity, that there was a gradual but constant increase of myopia from the primary schools up to the universities. Among the children of the primary schools he found but 6.7 per cent. of myopia, while in the gymnasium classes it had increased until nearly thirty per cent. (26.2 per cent.) were myopic. Professor Erismann, of St. Petersburg, also, in a like examination of the eyes of more than four thousand pupils (4358) found a steadily increasing percentage of myopia in going from the lower to the higher classes. He has delineated his results in the diagram—*vide* Fig. 2.

The figures on the left of the diagram indicate the percentage of emmetropia, hypermetropia, and myopia found in the several classes, ranging from the primary or lowest class up to the seventh class;

the latter representing students in about their eighteenth year. The classes are indicated by the numerals beneath the diagram. The curves of hypermetropia and myopia have for us the greatest interest, inasmuch as that of emmetropia remains

Fig. 2.

nearly stationary throughout. We find, however, that of seventy per cent. of hypermetropes in the primary classes there remain only thirty-five per cent. in the fourth, while the curve of myopia, starting with but twelve per cent., mounts rapidly and continuously, until at the eighteenth year we find that nearly forty-five per cent. of the pupils are myopic.

Now, gentlemen, what does all this mean? Let me tell you at the outset that a near-sighted eye is usually a diseased eye, and the above-quoted results of Cohn and Erismann show us that this disease is in the vast majority of cases either acquired or increased during adolescence.

If you look by means of an ophthalmoscope into a normal eye, you will see, as the most striking object in the fundus, the entrance of the optic nerve, which is here presented to us, as it were, in an optical transverse section. The optic disk then in the normal eye appears as a more or less perfect circle bounded by a thin whitish line,—the so-called sclerotic ring; outside of this again is in many eyes a partial rim of black,—the choroid ring; beyond this again the eye-ground presents a peculiar reddish-brown color and a stippled appearance, mainly due to the even pigmentation of the sexagonal epithelium of the choroid. The color of the disk is of a delicate pinkish red, owing to the capillaries ramifying in the nerve-tissue. A little to the nasal side of its centre there emerge from it the central artery and vein of the retina, which immediately divide into branches, spreading throughout the entire retina, the larger twigs, however, avoiding the point of sharpest vision, the macula lutea. This in healthy eyes on the upright image is frequently marked by a small yellow spot at the fovea centralis, surrounded by a circle more darkly pigmented than the rest of the eye-ground. Although, as before mentioned, this portion is avoided by the larger arteries and veins of the retina, it is most abundantly supplied with capillaries. The colored diagram which I have just shown you gives a clear idea

of the appearances. I wish you to look at it with sufficient care to impress its details carefully in your minds, that you may the better appreciate the anatomical changes depicted in myopic eye-grounds. In slight cases of myopia you will observe that the disk is more capillary, and that certain changes have set in on the temporal side. These at first consist of a disturbance of the choroid pigmentation—in places black, in others lighter than usual, the surface often presenting a ridgy or ploughed-field appearance. The area affected by these changes is usually cone-shaped, the apex pointing towards the macula. The choroid tissue at this point finally undergoes complete atrophy, its vessels disappear, its pigment is absorbed, and we have a thin layer of transparent membrane, through which we obtain a bright white reflex from the sclerótica. But the catalogue of pathological changes by no means stops here; the sclerótica now becomes softened by the long-continued chronic inflammatory processes in the vicinity, and bulges outward under the intraocular pressure, constituting the so-called staphyloma posticum. Inflammatory changes also take place in other portions of the choroid, as, for example, absorption of the epithelial pigment and atrophic patches of greater or less extent, accompanied by vitreous opacities. The vitreous opacities of course cause more or less hazy vision, the local atrophies blind spots (scotomata) in the field. These blind spots only too frequently occur at the macula, and thus destroy all useful vision, or the changes are accompanied by an exudation of serum lifting up the retina from the subjacent choroid, and thus detached it is incapable of long continuing its functions, and the patient becomes totally, hopelessly, blind.

This, gentlemen, is certainly a very serious state of affairs; but I would not have you believe that in all cases does myopia end thus disastrously. By no means is this the case; but in the vast majority of instances where it exists to any considerable degree there is impairment of vision; and such sad cases as I have above described, with either total blindness or what practically for all ordinary employments of life amounts to the same thing, are of only too frequent occurrence, and form one of the opprobria of ophthalmic surgery.

Such being the serious consequences of myopia and its marked tendency to progression, it becomes important to know the causes which are fruitful in its production and increase, that we may as far as possible prevent them.

If an eye be used continuously it becomes congested, just as do all the other organs of the body with physiological use: *e.g.*, in the stomach during digestion the mucous membrane becomes red and congested in the performance of its function—the secretion of the gastric juice; and, as every one knows, the muscles during muscular activity are supplied with increased quantity of blood, which, if long continued or frequently repeated, leads to their rapid increase in size. So it is with the eyes. During their use the choroid and retina become congested—red, from the increased flow of blood to the part. This physiological congestion during the performance of function is the rule with all the

organs of the body, and, like all physiological processes, lapses once more into comparative quiet when the normal stimulus is withdrawn.

The result, however, is quite different when even *normal* stimuli to organic functions are too vigorously applied or too long continued,—when *use* passes into *over-use*. Then what was at first a *physiological* congestion may become the foundation of *pathological* change.

Pre-eminently is this true with our eyes after long-continued use for near work, for there is then required a protracted strain upon the accommodation and convergence. A normal eye, however, under suitable conditions, may even undergo protracted use and experience no injury, the congestion subsiding entirely under rest. When subjected, however, to continuous use under unsuitable conditions, the result may be different, and these unsuitable conditions are too frequently represented in our schools, where from insufficient light or badly-constructed seats and desks the children are compelled to hold their books too near the eyes, thus necessitating an undue strain upon the ciliary muscle and the internal recti, and causing congestion of the eye. The above-named muscles, also, by their conjoint action increase the intraocular pressure, and cause a gradual lengthening of the antero-posterior axis by the giving way of the eyeball at its weakest point, which experience proves to be the region of the optic nerve entrance. At this point and usually at the outer side of the nerve the sclerotic coat is bulged backward, undergoing a corresponding thinning; the choroid, too, loses its pigment and becomes atrophied, causing this protuberant portion of the eyeball to become translucent.

Then, too, the congestion may be increased by position, the blood gravitating to the eyes when the head is bent strongly forward. You are all familiar with the varicose veins of the lower extremities, which so frequently result from too long standing, the coats of the veins distending under the continuous pressure of the column of blood. We have also a striking illustration of the same in inflammations of the extremities, and in the severe pain which ensues when such inflamed parts are allowed to remain long in a depending position. These are but illustrations of the blood gravitating to dependent parts; and if we hold our heads downward the rapid flushing of the face and suffusion of the eyes from stooping are matters of daily experience with us all. This condition is largely aided by anatomical conditions. When the head is bowed forward the neck is flexed, and with it the jugular veins. The return-circulation through them is thus retarded, leading to undue fullness of the lateral sinuses of the brain, and thus backing up the blood in the ophthalmic veins, and consequently congesting all the internal tunics of the eye. Thus position may promote congestion and softening of the choroid and sclerotic coats, and help on pathological changes within the eyeball.

Now, gentlemen, if such causes lead to pathological changes in a sound eye, how much greater danger do they present to a sick one! Thus, starting with a myopic eye, which, as I have told you, is

usually an unsound eye, how much more surely and rapidly will they augment the already existing weakness, and how important that every precaution should be used to obviate its increase!

But little attention has been paid to this important branch of hygiene in our schools, counting-rooms, and workshops. In our schools the children are too frequently compelled to spend the school-hours sitting at desks in which no regard has been paid to the relation between the height of the desk and seat: thus, for example, the chair being so high that the child cannot support its feet upon the floor, it seeks to avoid the fatigue of sitting upright without support, and, in order to bring its eye sufficiently near to the book, bends forward and rests on the desk; or, on the other hand, the desk is relatively too high, and the book thus forced up uncomfortably near to the eyes causes an unnecessary strain upon the accommodation and convergence, resulting in the chain of events I have described to you. Another source of great evil is insufficient light, not only in our schools and churches, but in the buildings devoted to the various mercantile and mechanical pursuits. We all know how in reading by twilight we are forced to approach the book to the eye in order to compensate for the indistinct vision by the larger retinal images, and thus at the same time cause increased strain upon the eye by the accommodation and convergence for this nearer point. The same causes are operative to a less degree in every badly-lighted room, and to make sure of a good light there should be at least three hundred square inches of glass allotted to each scholar in the room, and much more than this where the light is excluded by artificial or natural causes,—*e.g.*, high buildings close at hand, trees, etc. There should also be a frequent change of occupation during study-hours,—thus, from close application over books to other exercises, as recitations, lecture, intermission, etc. I have spoken principally of children in our schools, because it is here that we can accomplish the most good; but in our workshops and counting-rooms, factories, etc., the employees are continually working with insufficient light, and here too there is ample room for reform.

Ordinarily, in reading, the book should be held at from 12" to 14" from the eye; and to enable us to do this we must not only have a good light, but the type must be distinct and of a sufficient size. Putting small type into the hands of our school-children is false economy. Suppose, however, that your patient is unable to read at this distance (12"-14"), that he has become near-sighted, etc., that the ophthalmoscope shows an abnormally red nerve and a commencing or perhaps tolerably developed conus (staphyloma posticum), that the eye is unduly sensitive to a strong light, that it becomes red and painful after use. You have perhaps an example of so-called *progressive myopia*, and one which demands at your hands the most careful attention. In treating such a case, the first indication is to diminish the congestion of the eye by absolute rest. This may be attained by the use of moderately dark smoke-tinted glasses, by putting the ciliary muscles at rest, by repeated instillations

of atropia, and by forbidding all use of the eyes. I say "forbidding all use of the eyes," because although atropia, by paralyzing the accommodation, will effectually prevent all use of an emmetropic or hypermetropic eye, your patient, if he have a high degree of myopia (*e.g.* $\frac{1}{2}$ or more), will still be able to read by holding the book at his far point. The use of atropia will, however, successfully combat the cramp of the ciliary muscle so often accompanying this condition, and put it in a state of complete rest, and the degree of myopia will therefore appear to be diminished. The careful experiments of Dr. Schiess-Gemuseus in a considerable number of cases show, however, that atropinization even continued for six weeks probably does not otherwise alter the state of true refraction. But it undoubtedly by helping to secure absolute rest does give the inflammatory changes taking place at the posterior pole of the eye a chance to subside, and the eye to recover from its irritation.

A very important point in the treatment of myopia is the use of correcting-glasses. When the eyes have become quiet,—*i.e.*, the myopia is stationary,—for the purposes of distinct vision it is essential to wear a concave glass. But a myope, gentlemen, should never be allowed to select his own glass, for he will almost invariably select one which is too strong, to overcome which will always demand an unnecessary strain upon his accommodation, and thus become a source of danger to his already weakened eyes. For distant vision he will require a glass of sufficient strength to correct entirely his myopia,—*e.g.*, if by examination you have ascertained his myopia to be $=\frac{1}{2}$ in order to see distant objects distinctly, he will require a concave glass of twelve inches focus ($=-\frac{1}{2}$); with this, if his acuteness of vision be unimpaired, he should be able to see distinctly No. XX. of Snellen's types at twenty feet. It now becomes an important question to decide whether he shall wear the same glasses both for distant and for near work. While they correct his eyes for distance, it is only by an effort of the accommodation that he can see near objects distinctly. If he is young, with a good range of accommodation, if the choroidal changes are not marked, and if there is no marked tendency to progression, I am in the habit of allowing him to use the same glass for all purposes. If on the other hand the patient has reached middle life, or has a myopia still tending to increase, you must give him two pairs of glasses—the one for distance, which, as we have seen, entirely corrects his short sight, the other of sufficient strength only to place his far point at a convenient distance for his work. For example, if he have a myopia $=\frac{1}{2}$,—*i.e.*, his far point is seven inches from the eyes,—for distance you would prescribe for him $=-\frac{1}{2}$, but for reading or ordinary fine work you would ordinarily want to place his far point only slightly farther from his eye,—*e.g.*, to remove it from 7" to 14". In order to accomplish this, you would subtract the *desired* far point from that already existing, which in the case we have supposed is 7"; therefore $\frac{1}{2} - \frac{1}{4} = \frac{1}{4}$, so that in order to give him $M = \frac{1}{4}$, or, what is the

same, place his far point at 14", we would prescribe glasses — $\frac{1}{4}$ for his near work.

Thus, gentlemen, we have cast a rapid glance at the causes which in every civilized community are constantly producing defects of sight, and which so uniformly increase the already large number of near-sighted individuals. If I have succeeded in impressing on your minds the fact that near-sighted eyes are usually sick ones, and have secured your co-operation in endeavoring to improve the schools and workshops of your immediate vicinity according to the principles above enunciated, I shall have the satisfaction of feeling that I have done much to diminish the quota of sick eyes among our population.

ORIGINAL COMMUNICATIONS.

ON LIGATURES: AN ATTEMPT TO DECIDE ON THE BEST MATERIAL FOR THE LIGATION OF ARTERIES.

WITH EXPERIMENTS.

BY JOHN R. HAYNES, M.D.,

Philadelphia.

(Continued from page 535.)

METALLIC LIGATURES.

IN 1814, Dr. Physick, noticing the immunity with which balls were sometimes lodged in the human tissues, was led to propose the use of metallic threads for the ligation of arteries. It does not appear that he ever put his idea into practice; but Levert, of Alabama, in 1828, was induced by his suggestion to make a number of experiments, with the view of elucidating the action of metallic ligatures in the lower animals.

The use of metallic sutures has had such an important influence in bringing about the employment of ligatures of a similar composition, that a few remarks on this subject do not seem out of place. Purmann, of Germany, in the last century, used silver sutures in wounds of the tongue; and Mihles, of England, used silver and gold thread in hare-lip. In this deformity, Percy, of France, used lead, or gold or platinum covered with lead. Dieffenbach, the great German surgeon, in 1826, advised the use of lead wire in staphyloraphy. In 1831, Mettauer, of Virginia, published a case of ruptured perineum in which the lead suture was successfully employed; and in 1847 he detailed the successful results of the employment of lead wire in vesico-vaginal fistula. In the later operation he had, however, been anticipated by a London surgeon named Gosset, who, in 1834, cured a long-standing case of vesico-vaginal fistula by paring the edges and uniting them with silver wire coated with gold.*

Marion Sims, of New York, in 1852 began to urge the claims of silver wire as a suture generally, and especially in cases of vesico-vaginal fistula, with such enthusiasm that metallic sutures came into very general use, and may now be considered as established in many operations.† In fact, before

their introduction, the cure of a case of vesico-vaginal fistula was almost, if not quite, unknown. In proof of the unirritating character of silver sutures, Prof. Agnew states that he has known them to remain *in situ* after the operation mentioned for three months without producing the slightest disturbance;‡ and Redfern Davies recorded a case of staphyloraphy in which a silver suture was left in place for four years with equal immunity.§

Induced by such facts as these, Simpson, in 1858, made use of ligatures of platinum wire in a case of excision of the breast. The wound was closed by metallic sutures, and collodion applied. Healing by granulation ensued, and the ligatures were thrown off during the process of suppuration.|| In the subsequent year, Dr. Emmet, of New York, repeated Simpson's experiment, using silver wire instead of platinum. The result will be given under the proper head.

Iron-wire ligatures were used by Holt, of London, in 1864, in three cases of excision of the breast, one of amputation of the arm, and another of the leg. Twenty-nine ligatures were used, none of which were seen to come away. In no case was union by first intention secured. Iron-wire ligatures, the ends of which were left hanging from the wound, were used in two cases of amputation by Langenbeck. They came away after a longer interval than when silk is used.

SILVER LIGATURES.

Experiments on animals.—Levert was the first to make experiments with silver and other metallic ligatures. He tied the carotid in two dogs, and the femoral in a third, with silver. In all three cases the wound healed by first intention, and, on dissection, it was found that "the silver had become encysted."¶ He does not state whether the ligatures were found *in situ*, or whether the vessels had been cut through. Gold and platinum acted in the same manner as silver.

Sir James Y. Simpson, in 1858, repeated these experiments, employing silver and numerous other metals. He never published a detailed account of his experiments, but stated, in his work "On Accupressure," that the results corresponded with those of Levert. "The metallic loops remained in their original situation around the obliterated point of the artery, with no apparent tendency to displacement or ejection, and the metallic threads were intimately blended in and among the effused lymph and tissues." He found that none of the metals produced suppuration, while silk almost invariably did.

Kellburne King states that he has repeated Levert's experiments, with similar results.**

But by far the most elaborate experiments on silver wire have been those of Professor Howard,†† on the carotid arteries of sheep. The interesting

† Lectures on the Treatment of Wounds, delivered at the University of Pennsylvania.

‡ Lancet, Feb. 28, 1873.

§ Edinburgh Medical Journal, July, 1858, p. 76.

¶ Loc. cit.

** Lancet, October 6, 1866.

†† Op. cit.

† See Agnew on Vesico-Vaginal Fistula, passim.

character of his observations is unquestionable, though the deductions drawn from them are not to be considered as proven.

Subjoined is a table, giving the results of these experiments. The ligature, as is indicated, was tied with various degrees of tightness. In all cases it caused the formation of a capsule of lymph around the spot to which it was applied, and the artery was closed in every instance.

NO.	DEGREE OF TIGHTNESS OF LIGATURE.	RESULTS OF DISSECTION.	INTERVAL BETWEEN OPERATION AND DISSECTION.
1	Very tight.	Suppuration at point of application. Ligature extruded.	22 days.
2	Not quite so tight.	Suppuration at point of application. Ligature on its way to surface.	
3	Tight enough to secure apposition, but not wound artery.	Suppuration at point of application. Ligature on its way to surface. (In these three cases the ligature was applied to the same artery, at short distances from each other.)	
4	Tight.	Ligature found enclosing a slough in cavity of abscess.	56 days.
5	Artery two-thirds closed.	No suppuration. Ligature <i>in situ</i> , enclosed in a solid mass of lymph.	37 days.
6	Same.	No suppuration. Ligature <i>in situ</i> , enclosed in a solid mass of lymph.	23 days.
7	Same.	No suppuration. Ligature <i>in situ</i> , enclosed in a solid mass of lymph.	10 days.
8	Same.	No suppuration. Ligature enclosed in a capsule. It had divided the external coat, and was in contact with the middle coat; vessel obstructed by a firm clot.	10 days.
9	Same.	No suppuration. Ligature could not be found; some fibro-cellular tissue at point of application; artery occluded.	14 months.
10	Same.	No suppuration. Ligature <i>in situ</i> , in small capsule. Artery solid and hard for some space. Same appearance as in No. 10.	10½ mos.
11	Same.	No suppuration. Ligature <i>in situ</i> , covered by a thin layer of lymph. Artery not obstructed by clot.	13½ mos.
12	Applied so as not to obstruct vessel at all.		

It will be noticed that in the instances in which the ligature was applied firmly, or even drawn so as to bring the walls of the vessel in apposition, suppuration ensued. In this respect these experiments differ from all previous ones, and from those of the writer. Howard attributes this discrepancy to the alleged fact that sheep approach more nearly to man in regard to vulnerability; whereas, he says, dogs, on which most of the previous experiments have been made, are notoriously tolerant of injury. That sheep are less tolerant of injury than dogs may fairly be disputed, seeing that in all of Howard's experiments the wound healed by first intention; whereas, in Lever's dogs, the reverse was frequently the case. Moreover, Simpson's experiments were made on a large variety of domestic animals, yet his results agree with Lever's.

When we examine these experiments of Howard's more closely, we see that they are not in all respects fair. Thus, the first three were made on the same vessel, the ligatures being applied within a short distance of each other, and the sheath being necessarily much disturbed; hence we cannot wonder at

suppuration ensuing. If, then, we eliminate this unfair experiment, we have only one instance in which the tightly-drawn silver caused suppuration, and that is scarcely enough to support the entire weight of Dr. Howard's theory, that the firm application of the silver ligature is the sole cause of the mischief which follows its use.

The remaining eight experiments were not altogether successful in proving that the slack silver ligature will remain *in situ*; for in one, at the end of ten days, the external coat had been divided, and in another, when the parts were examined at the end of fourteen months, the ligature could not be found, having evidently worked its way to the surface.

Professor Howard, as a practical application of the results of his experiments, considers that the best way to ligate an artery for aneurism is to diminish its calibre two-thirds with a short silver ligature. The single case in which this plan was tried certainly did not terminate encouragingly, for the man died of hemorrhage.

Experiments of the Writer.

Exp. X.—A coil of silver wire, eighteen inches long, was placed in the peritoneal cavity of a cat, and the wound closed with one deep and three superficial silver sutures. The wound healed by adhesion, and the superficial sutures dropped out without suppuration. A hard swelling formed at the spot, and in fifty-nine days its apex opened and discharged a little pus, and in a few days healed again.

On the seventy-third day, the animal was dissected. The coil of silver was entangled in the omental layers, surrounded by an indistinct transparent membrane. The swelling at the site of the wound consisted of a mass of lymph enclosing in its centre a little pus and the deep suture, which was long and sharp-pointed.

Exp. XI.—A portion of the muscular mass forming the thigh of a cat was surrounded subcutaneously with silver wire. Profuse suppuration ensued, and on the twenty-fifth day as much of the wire as possible was taken out. It was much bent and twisted. The parts now healed.

On the seventy-fifth day, dissection revealed a piece of wire about an inch long imbedded in the muscle. No traces of a cyst existed.

Exp. XII.—A small coil composed of one foot of silver wire, so disposed as not to present any sharp points, was placed under the integument of a cat's shoulder, and the wound closed by silver sutures. The incision healed without suppuration; the sutures were removed on the tenth day. An abscess formed, and burst on the twenty-eighth day, giving exit to a small quantity of pus. In a few days more the silver was extruded, after which the ulcer immediately healed.

Exp. XIII.—Small coils (made as nearly as possible of the same bulk) of the following materials were placed in cavities under the skin of the side of a large cat, each opening being closed with a stitch of the corresponding material: silver, lead, iron, saddler's silk, carbolized silk, linen thread, catgut of the thickness of saddler's silk, carbolized catgut of the same dimensions, and carbolized catgut a size thicker; the wounds all healed without suppuration.

In forty-two days the animal was dissected. The silver was enclosed in the cavity of an abscess; the thick carbolized catgut was not present, having been extruded by suppuration on the tenth day; a few shreds of the other two pieces of catgut (carbolized and non-

carbolized) were found enclosed in small cysts. The lead, iron, linen, and both kinds of silk were each enclosed in a very thin transparent capsule, and had not caused the slightest irritation.

Exp. XIV.—The carotid of a dog was tied firmly with silver wire. The wound was sewed up with a continuous suture of carbolized catgut. On the fourth day it was necessary to cut several stitches to allow some pus and serum to escape, after which the wound healed rapidly. In fifty-three days the parts were examined. The ligature, enclosed in an indistinct cyst, lay immediately beside the artery, which was slightly indented at the point of ligation, and after being laid open was found to be obliterated to the extent of three lines.

Exp. XV.—The carotid of a cat was tied firmly with silver. The wound was closed with a continuous suture of hemp; it healed slowly, from the animal tearing out the suture.

In twenty-seven days the parts were examined. The ligature had nearly cut through the vessel. It was covered with a thin pellicle of organized lymph.

Exp. XVI.—The carotid of a cat was tied firmly in two places, one-quarter inch apart, with silver wire, and divided between the ligatures. The incision, which had been closed by a continuous stitch of fine sewing-silk, united by first intention.

In thirty-six days the animal was dissected. The silk suture was still in place, having created no irritation whatever. The ends of the vessel were united by a band of organized lymph about half an inch long. The lower ligature had cut its way through the artery, and was lying near it enclosed in a thin transparent cyst; the upper ligature still surrounded the vessel, and was enclosed similarly.

Exp. XVII.—The carotid of a cat was surrounded in two places with silver wire drawn with sufficient firm-

ness merely to diminish the calibre of the vessel two-thirds. The wound was treated as in the last experiment, and with the same result.

In fifty-one days the parts were examined: the upper ligature was still *in situ*; the lower had cut its way through the artery, and was lying near it; the position of its application was shown by a delicate cellular interval; both ligatures were covered by a thin membrane.

Exp. XVIII.—The left common iliac and the abdominal aorta of a cat were each surrounded by a silver ligature, applied so as not to stop pulsation, but, so far as could be guessed, to diminish the calibre about two-thirds. The sheath of the vessels was not disturbed except just at point of ligation. The inguinal incision was closed by silver sutures; slight superficial suppuration ensued, but healing was complete in a few days.

In sixty-three days the parts were examined; a large cyst was present at the point of ligation. On opening, it was found to contain imperfectly laminated blood-clots, and lying loose at its bottom was the aortic ligature. The aorta communicated with the cyst, and was patulous in both directions. The iliac ligature was found loose in a small cavity in the side of the cyst; it had divided the vessel, which, however, was obliterated.

RESULTS OF THE USE OF SILVER LIGATURES ON MAN.*

1. *Ligation of Arteries in their Continuity.*—Stone, of Louisiana, in 1859, was the first to make this application of silver, but without decisive results, on account of the speedy death of his patient from dysentery. In the following table will be found the details of all the cases published in which silver wire has been applied to arteries in their continuity.

NO.	OPERATOR AND REFERENCE.	AGE.	ARTERY TIED.	DISEASE.	SUBSEQUENT HISTORY OF THE CASE.
1	F. Maury. Phila. Med. Times, March 29, 1873, p. 404.	52	Right subclavian (third part).	Axillary aneurism.	The degree of tightness of the ligature is not stated. The man did well until the eleventh day, when secondary hemorrhage occurred. During the first and second attacks he lost more than a pint of blood; during the third, which occurred on the same day, the blood gushed out in a full stream, and in about three hours the man died. "The post-mortem showed the ligature in good position, and just ulcerating through. The subclavian artery was in part filled with a fibrinous coagulum, and partly with a soft clot, evidently more recent, from the innominate to the ligature." It is said that the aorta and heart were in an advanced stage of fatty degeneration; but, by a strange omission, the condition of the walls of the ligated artery is not given.
2	T. Smith. Holmes' System of Surgery, vol. iii.		Radial.		The wire had to be cut away in about three months, on account of "the inconvenience it caused the patient."
3	Stone. Am. Jour. Med. Sci., Oct. 1859, p. 570.		Common iliac.	Inguinal aneurism.	Wire drawn with sufficient firmness merely to stop pulsation. Death from dysentery on the twenty-sixth day. No autopsy.
4	Pollock. Lancet, Sept. 22, 1866, p. 328.	51	External iliac.	Femoral aneurism.	Ligature drawn tight enough merely to bring sides of vessel in contact. In three days the man died from bronchitis. On autopsy, it was found that the wound had not commenced to heal. Coats of vessel perfect. Decolorized and partially adherent clots above and below the ligature.
5	C. H. Mastin. New Orleans Med. and Surg. Reporter, Sept. 1866.		External iliac.	Inguinal aneurism.	The wire was tied with a double knot tightly enough to stop pulsation only; the ends were bent down, and turned into the sheath. The wound healed by first intention. Perfect recovery ensued. Nothing has ever been seen of the ligature, though the man is still under observation.
6	T. Holmes. Lancet, Sept. 22, 1866, p. 328.	43	Femoral.	Traumatic popliteal aneurism.	Wire drawn tightly enough to stop pulsation merely. On the seventh day the wound was nearly, and on the twelfth quite, healed. On the fifteenth day he left the hospital. Nothing was ever seen of the ligature, though the man was under observation for two years.
7	Kellburne King. Lancet, Oct. 6, 1866, p. 400.			Aneurism.	The writer merely states that he ligated the artery with silver, and that the operation was satisfactory so far as the ligature was concerned, but that the patient died of rupture of the sac.
8	Kellburne King. <i>Loc. citat.</i>			Aneurism.	No details are given, except that hemorrhage occurred on the eighth day; that silk ligatures were applied above and below the silver ligature, and the patient recovered.

* Except in some cases of Erichsen's, which will be mentioned, where silver ligatures were used, they were always cut short and buried in the wound.

NO.	OPERATOR AND REFERENCE.	AGE.	ARTERY TIED.	DISEASE.	SUBSEQUENT HISTORY OF THE CASE.
9	Brodhurst. Trans. Path. Soc. London, vol. xviii. p. 67.	46	Femoral.	Femoral aneurism.	The ligature was applied "loosely." On the seventh day, wound nearly healed; on the tenth day hemorrhage occurred, but was controlled by a pad for a few hours, when it recurred. The artery was now tied higher up with two silver ligatures. On the twelfth day hemorrhage recurred, and a silk ligature was applied on the proximal side of wound. On the thirteenth day the man died of exhaustion. On autopsy, it was found that the ligature first applied had cut its way seven-eighths through the vessel, the distal orifice of which was patulous. The three other ligatures were intact on the proximal end of the vessel, which was occluded. The arterial system was degenerated.
10	Benjamin Howard. Trans. Am. Med. Assoc., 1872, p. 559.		Femoral.	Popliteal aneurism.	The wire was drawn so as to diminish calibre of artery two-thirds. Wound healed by first intention, except at one end; pulsation ceased in aneurism. On eleventh day, walked a considerable distance. On seventeenth day, hemorrhage. On nineteenth, a silk ligature was applied below Poupart's ligament. The history of the case from the seventeenth day is very imperfect, but the reporter was informed that five or six days after the application of the silk ligature the man died of hemorrhage.
11	Redfern Davies. Lancet, Feb. 28, 1868, p. 233.		Popliteal.	Elephantiasis Arabum.	The ligature came away on the twenty-first day. The patient recovered so far as the operation was concerned.

Several additional cases are referred to in Prof. Gross's work on Surgery, and the reader is left in doubt as to whether the ligature was encysted or not. In a conversation with this author, he stated as the result of his experience that the ligature came to the surface, though after a longer interval than in the case of silk.

In Mr. Holmes's "Lectures on Aneurism" he states that the only satisfactory case on record is his own (No. 6). If we also except Dr. Mastin's case (No. 5), of which the talented lecturer seems strangely ignorant, certainly our experience with silver ligatures in the treatment of aneurism is anything but satisfactory.

Of the remaining nine cases tabulated, three (Nos. 3, 4, and 7) died of causes unconnected with the ligature; secondary hemorrhage occurred in four cases (Nos. 1, 8, 9, and 10), in three (Nos. 1, 9, and 10) of which it proved fatal; in one case (No. 11) the ligature came away just like the ordinary ligature; and in another (No. 2) it had to be cut out.

2. *Silver Ligatures in the Abdominal Cavity.*—Peaslee states that he has seen several attempts to apply silver wire to bleeding vessels in ovariectomy, but without success; the ligature slipped off as soon as applied.* Sims informs us† that for the last ten years he and his colleague, Dr. Emmet, have, as a rule, in this operation, secured the pedicle with silver wire and returned it to the abdominal cavity without any bad result ensuing. The latter gentleman has published the details of two cases thus treated, both recovering without a single bad symptom.‡ However, the evidence in favor of silver thus applied is not so strong as that on the side of silk; for in the first case we have little more than a general assertion, while in the latter we are supplied through the industry of Peaslee with the fullest information. Prof. Agnew mentions a case which came under his observation in which he attributes the death of the patient to the application of a silver ligature to a wounded omental artery.§

3. *Application of Silver to Arteries* divided in Operations.*—Platinum ligatures, as we have seen, proved not a whit superior to silk in the hands of Simpson. In Dr. Emmet's case, already referred to, silver was used with somewhat better success, though we are left ignorant of the ultimate disposition of the ligatures.

The breast of a woman, aged 31, was excised for scirrhus. Eleven silver ligatures were applied by twisting. The wound was accurately closed by whipped silver sutures. Healing by adhesion occurred nearly throughout, but the dependent angle of the wound required to be kept open to allow of the escape of some pus, which the author thinks was formed "in consequence of the death and suppuration of the portion of tissue strangulated by the ligature." On the eighth day a portion of the suture midway was found to be torn out. The fissure thus formed healed by granulation, so that by the fifteenth day the wound was entirely healed. The suture was not removed until forty-three days had elapsed. The most careful examination failed to reveal the position of any of the ligatures, though none had escaped.||

Dr. F. D. Lente has published a similar case:

Mrs. M., breast removed, for scirrhus; ten silver and one silk ligatures applied; wound closed by five silk sutures. On the eleventh day a small abscess was opened; on the fifteenth day there was slight discharge from the lower end of wound, the remainder of which was healed. On the fifty-fifth day "a loose wire was felt floating about in situation of abscess," and was removed by a small puncture.¶

In amputations of the extremities silver ligatures have been used by Erichsen and Lente. The former writer gives his experience thus:

"If the ends of the wire were left out of the wound, the noose became imbedded in a mass of plastic matter, did not separate, and, after several weeks, required considerable force to detach and disconnect it. If the ends were cut short, the sides of the wound healed over them; they became encapsuled, but by no means innocuous; in some cases giving rise to severe neuralgia of the stump by pressure on and irritation of neighboring nerves; in others after some weeks causing localized circumscribed abscesses to form."***

¶ American Journal of the Medical Sciences, April, 1869, p. 309.

** System of Surgery, vol. i. p. 281.

Our talented countryman, Dr. F. D. Lente,* has given us more detailed information on this portion of the subject. A short account of his cases is given, that the reader may be enabled to judge for himself of the merits of the method:

1. Re-amputation of the thigh—nine short silver ligatures applied. Six hours afterwards stump bled profusely. An assistant opened the stump and tied four or five vessels with silk. He saw nothing of the silver ligatures, and *thought* that the vessels he tied were not those to which the silver had been applied. On the fifty-first day, the note states, the wound was healed and gave no trouble.

2. Amputation of fore-arm—six short silver ligatures applied. Lips of wound brought together by fine silk sutures. Antiseptic dressing. "Considerable oozing of dark, bloody matter" while dressing wound. Eighth day, wound suppurating; oozing of dark blood continues. Thirty-ninth day, stump soundly healed and gives no trouble.

Of the third case (amputation of leg), and the fourth (of the arm), the note merely states that suppuration of the wound occurred, and that recovery was slow.

It will be seen that the first two of these cases were complicated by secondary hemorrhage.

In one of them, indeed, one cannot avoid a strong suspicion that some of the ligatures slipped from the ends of the vessels. It is not stated that the wires did not come away, though we are led to infer that such was the case.

Finally, we are left in the dark as to whether any subsequent trouble, such as Erichsen indicates, occurred.

Dr. Lente was kind enough to respond to inquiries concerning his subsequent experience with silver ligatures, substantially to the following effect:

1. Their use requires the aid of an intelligent assistant.
2. He does not claim that "any larger proportion of cases heal by first intention than by other methods."
3. In amputations "most of the ligatures come away." They may easily escape notice on account of their small size. "In other operations, when union by first intention fails, the number that comes away depends on the amount of suppuration and of granulating surface. The proportion is very small."†

LEAD LIGATURES.

As with silver, Levert was the first to experiment with lead-wire ligatures.

1. He tied the carotid of a dog firmly with lead wire. The wound healed by granulation. On dissection, in forty-three days, the lead was found encysted near the artery, which was entirely removed for the space of one-half inch. Both ends of the vessel were firmly sealed with organized coagula.

2. The same experiment repeated. On dissection, after twenty days, the ligature was found encysted and surrounding the remains of the vessel. In three similar experiments, identical results were obtained after intervals respectively of twenty-nine, twenty-two, and twenty-seven days.

Howard obtained opposite results in his experiments with sheep, but, as will be seen, the ligatures, except in one instance, were quite bulky. Consequently, his observations cannot be accepted as fair evidence in favor of the idea that lead is more irritating to the tissues than silver.

1. Thick lead wire was applied to carotid, and drawn so as to bring its walls in contact. The ends of the ligature were enclosed in perforated shot, and the wound closed. In twenty-seven days, examination showed the ligature, enclosing a slough, in an abscess, which was making its way to the surface.

2. A thin lead band was used, with a like result after thirty-seven days.

3. Carotid closed two-thirds by lead ligature, with a like result after thirty-six days.

Experiments of the Writer.

Exp. XIX.—A coil composed of one foot of lead wire was placed under the skin of a cat's shoulder, and the incision closed by a single lead suture. The wound healed, and the suture dropped out without suppuration. On examination, fifty-one days after, the coil was found enclosed in a thin transparent cyst.

Exp. XX.—The carotid of a cat was surrounded with lead wire, drawn rather loosely. The incision was sewed up with a continuous suture of carbolized catgut, and carbolized dressings applied. In three days wound was suppurating profusely; granulations sprang up, and it was healed by the fourteenth day. On examination, thirty days after, the ligature was found *in situ* within an indistinct capsule. The artery was obliterated.

Exp. XXI.—The carotid of a cat was tied firmly with lead wire, and the wound drawn together by lead sutures. It healed by first intention, and the sutures dropped out. On dissection, thirty-one days after, the lead had passed through the artery (which presented no break in its continuity), and was enclosed in the cellular tissue about two lines from it.

Exp. XXII.—The carotid of a large dog was tied firmly with lead, and one inch above with catgut (non-carbolized). The sheath was not disturbed in the interval. Hempen sutures were used. They were soon torn out by the animal, so that several days elapsed before the wound was healed. On examination forty days after, neither ligature could be found. The lead had probably made its way to the surface, and the catgut been absorbed. The artery was obliterated between the joints of ligation, but presented no break in its continuity.

Exp. XXIII.—Equal bulks of lead wire, silver wire, silk, and carbolized catgut were placed in corresponding positions in the muscles of different cats. In thirty-two days the animals were dissected. The lead was found enclosed in a thin cyst; the silver was also in a cyst, which contained in addition a few drops of pus; the silk was likewise encysted. The carbolized catgut was not present, having escaped by suppuration on the fourteenth day.

THE USE OF LEADEN LIGATURES ON MAN.

Professor Agnew applied a leaden ligature to the brachial artery in a case of aneurism of that vessel.‡ Perfect and rapid recovery ensued, the wound healing by first intention, and the ligature never making its appearance. The happy termination of this case (which is the only one that has come to the writer's knowledge of the use of lead as a ligature in the human subject) makes it desirable that an extended trial should be given to lead in cases of aneurism. Certainly, experiments on animals prove lead to be of an exceedingly unirritating nature.

(To be continued.)

EXTENSIVE INJURY TO THE LARYNX, TRACHEA, AND ŒSOPHAGUS; AND RECOVERY.

BY C. H. BOGMAN, M.D.,

Salt Lake City, Utah.

JUNE 18, 1869, I was summoned to attend W. A. P., aged 57, who had attempted suicide by cutting his throat. Two hours subsequent to the attempt I found him held upon the bed by several men, and, with the strength of a maniac, endeavoring to tear open the wounds in his throat.

He was suffering from acute mania, of which the suicidal attempt was the first symptom noticed by his family.

Upon examination, I found two wounds; the superior dividing the larynx for full half its diameter through the thyro-hyoid membrane, and the inferior completely dividing the trachea just below the cricoid cartilage, and also opening the anterior walls of the Œsophagus by an incision five-eighths of an inch in length. Both incisions were made with a large-bladed, keen-edged pocket-knife. The large vessels of the neck were uninjured, and the hemorrhage from three small vessels in the inferior flap was controlled by direct pressure.

Having ligated the vessels, and thoroughly cleansed the parts, the wound of the Œsophagus was united by three fine silk sutures, the knots being tied in such a manner as to be inside the Œsophagus.

The inferior wound of the trachea was then closed by six coarse wire sutures, two placed postero-laterally to prevent their irritating the wound of the Œsophagus, two laterally, and two antero-laterally. The superior wound of the larynx was then closed by four wire sutures.

In both cases the sutures were made to include as much as possible of the superlying and attached fibrous and cellular structures, twisted as tightly as possible without strangulation of the included tissues, and the ends cut as short as was consistent with strength and permanence.

The external wounds were closed by silk sutures, and a wet compress covered the whole. Strips of adhesive plaster were applied to the shaven head; their centres being on the occiput, and the head well flexed, their long ends were brought forward, crossed on the breast, and carried round to the lumbar region, the whole being arranged so as to prevent extension or rotation of the head.

He was then well secured, to prevent violence; morphia was exhibited hypodermically, and sedatives and aliments in solution, by means of a flexible tube, carried well into the pharynx. The medical treatment consisted principally of sedatives and tonics.

Recovery was slow and tedious. There was profuse suppuration from both wounds; the mania entirely disappeared on the eighth day, and left him greatly prostrated. The wounds were frequently syringed with the permanganate of potassium in solution.

In September, 1869, the wound was healed, except a small fistule in the thyro-hyoid membrane, through which a probe was readily passed into the larynx. Both voice and deglutition were greatly impaired.

At present (May 15, 1874), with the exception of a peculiar resonance, the voice is unimpaired; articulation is peculiar,—to use his own expression, "as if I had a hot potato in my mouth."

Deglutition is performed easily if the attention is directed to it, otherwise the food "goes the wrong way."

In other respects he is perfectly well. The fistule healed voluntarily; the encysted wire sutures are readily felt in the larynx and trachea. He has had no return of the mania, and expresses himself dissatisfied with the knife as a means of suicide.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

SERVICE OF PROF. H. C. WOOD.

Reported by E. T. BRUEN, M.D., Resident Physician.

CASES OF SCIATICA.

W. S. entered this hospital April 14, 1874, suffering from well-marked symptoms of sciatica. He has been more or less a sufferer for the past two years, while under the most varied treatment in different hospitals. A saline purge was ordered to be given every other day for a week, together with the following:

R Potass. acetat., ʒi;
Potass. iodidi, ʒii;
Aq. cinnamonom., fʒvi.—M.

Sig.—Tablespoonful t. d.

The daily use of the downward continuous current from eighteen cells was directed in addition; to be applied over the course of the nerve. After the first application of the electricity he said he felt greatly relieved, and in a period of ten days he could walk without pain, and was discharged cured April 30.

G. W., æt. 50, admitted to the ward April 20, suffering from the ordinary symptoms of sciatica, which he stated first attacked him two weeks previously. His pain was so severe that he could only walk with much difficulty, supporting himself with a cane. The continuous current of electricity from eighteen cells was employed, without any other treatment. He felt markedly benefited after the first two applications of fifteen minutes each, and could walk without his cane; at the expiration of ten days he was discharged perfectly cured.

CASE OF TAPE-WORM.

W. S., æt. 26, native of England, admitted to the hospital April 30, 1874. He states that he has had a tape-worm for some years; he has been in this country about three months, and during this time he has passed a number of links of it at intervals. He has been subjected to treatment for his worm several times in different London and Liverpool hospitals, and although large portions of the tape-worm had been obtained, the head had never been passed.

His occupation abroad was that of a game-keeper, and according to his own statement he has never eaten raw pork, beef, or meat of any kind. He is a strong man, his health having been only slightly affected; he complains, however, of headache, a sense of pain or uneasiness in the abdomen, with depression of spirits and nervousness, which prevent him from working; he has also a ravenous appetite. He was kept a few days in the house on restricted diet, after which the following treatment was instituted. A dose of salts (Rochelle), one ounce, was given one evening at five o'clock. No supper was allowed, excepting a glass of milk. The next day the following prescription was administered:

R Granati rad. cort.,
Pepo, aa ʒss;
Ergotæ, ʒss;
Ext. fil. mas, ʒi;
Pulv. acaciæ, ʒii;
Ol. tigllii, gtt. ii.—M.

Et ft. emulsion.

It occasioned slight nausea, and operated three times freely.

On examining the stool a tænia solium eighteen feet long was found expelled in a single piece rolled in a ball, knotted in at least ten knots. The links seemed to have parted close to the head, as they were very

small, but the head itself was not found, though the stools were examined with great care. As the man passed no more links, he was discharged at the end of a week.

TRANSLATIONS.

TRACHEOTOMY PERFORMED BY MEANS OF THE ACTUAL CAUTERY.—M. de St. Germain read before the Académie de Médecine, at a recent sitting, an account of the operation for tracheotomy as performed by him recently.

After some remarks relative to various experiments which he had made on different animals, M. de St. G. went on to say that this was the first opportunity which had offered for the trial of the procedure in a human being, and then gave the following details:

A child, 3 years of age, admitted to his wards January 26, 1874, for club-foot, was attacked by measles, followed by bronchitis. He was nearly convalescent from this disease, when he presented unequivocal signs of diphtheritic angina. Gray pseudo-membranous plaques appeared on the right tonsil, then on the left; finally, his voice was almost lost, and became decidedly croupy.

This was on February 23. On the morning of February 24 very marked difficulty in drawing the breath was noted, but no cyanosis. The usual treatment was resorted to, but without avail, and by evening the breathing had become much more difficult, and decided cyanosis had manifested itself.

Under these circumstances tracheotomy was determined upon, and the operation was carried out in the following manner. The child was placed upon a mattress-covered table, with his shoulders supported upon a sort of bolster formed of an ordinary pillow tied tightly around an empty bottle placed at its centre. The arms and legs being firmly fixed, an assistant held the head well back, so as to throw the larynx very prominently out. The operator having taken his position on the right of the patient, and having determined as exactly as possible the point corresponding to the crico-thyroid membrane, seized the larynx between the thumb and middle finger, and pressed it firmly on the deeper parts. This manœuvre had the advantage of isolating the larynx absolutely, and of making it perfectly immovable, as well as of rendering tense the overlying integument. (It might be said here that the immobilization of the larynx, during a period relatively quite long, has not the dangers which have been attributed to it. M. de St. G. had been able, in experiments made on various children, to render the larynx immovable without danger during a period three times as long as that necessary to perform tracheotomy.)

The larynx being fixed, the operator seized a small, thin-bladed probe, or rather dull-pointed bistoury, and, having brought it to a cherry-red heat by means of an enameller's lamp, introduced it slowly in a perpendicular direction, cutting from base to point, as had been determined, that is to say, immediately below the thyroid cartilage. Penetration was very easy, and a very slight sensation of resistance overcome indicated that the crico-thyroid membrane had been traversed. Then, the bistoury not having been removed, the cricoid cartilage and one ring of the trachea were divided, when the instrument was taken out. The existence of a very clean wound could then be noted, yielding no blood, and showing, at the deepest part, a black slit, the laryngo-tracheal incision. It might be noted that the usual sounds significant of air entering the trachea were not heard until the two-branched dilator was introduced, when hissing sounds were manifested.

The patient now respired easily, and the canula was

introduced at leisure, and with the greatest facility. When once introduced, however, the canula was found not to act. The cause of this was soon discovered in an enormous plug of false membrane stopping up its lower end. This being removed by coughing the moment the canula was taken out, the latter was again introduced, and secured by the usual methods.

(It may be remarked that during the whole of the operation the patient had not lost a teaspoonful of blood in all.)

The child was removed to a bed, surrounded with hot bottles, and watched with the greatest care. For two days all went well; on the third, however, it was ascertained that false membrane was forming still. The canula having been removed from the wound, the latter was found to present the usual appearance following tracheotomy. From this day the child gradually grew worse, and finally succumbed on the fourth day subsequent to the operation.

The autopsy showed considerable pulmonary congestion and emphysema, also a quantity of false membrane in the trachea, constituting a sort of cast. The wound looked natural, and the cauterization had not affected the lateral or posterior portions of the trachea.

The writer who reported M. de St. Germain's case in the *Gazette Médicale* asks two questions in relation to it. First, whether, if the bistoury should get cold, it might not act simply as an ordinary knife, thus leading to hemorrhage? Second, if, on the other hand, the blade should be a little hotter than usual, might not the cauterization of the cartilages lead to their necrosis? These questions remain to be answered. A. V. H.

TRANSFUSION OF BLOOD IN THE INSANE.—Prof. Meynert (*Wien. Med. Presse*) states that the operation of transfusion was frequently performed in England in the seventeenth century in patients suffering from mental affections, but that it could not be supposed that in such cases, even under the most favorable circumstances, the operation would be attended with favorable results.

In cases of melancholia, however, it might be possible to look for a favorable result from the operation, since the transfused blood might act as an irritant, and, like febrile affections, cause an intermission of the state of melancholy. In three cases in which the operation with defibrinated blood was performed by Redner, the pulse rose from fifty to eighty beats per minute, and two of the patients, half an hour after the operation, felt better, and were more cheerful; but this improvement was but transitory. A quarter of an hour later the pulse could scarcely be felt; vomiting, micturition, and defecation took place, followed by a chill of violent character, and fever of three days' duration. W. A.

INJURIOUS EFFECT OF HUMAN MILK UPON DOGS.—M. Devilliers stated in a report read before the Académie de Médecine on this subject that the researches which he had made proved human milk to possess the quality of rendering dogs rachitic.

Advantage had been taken of this circumstance in the employment of the milk of dogs for the nourishment of young children suffering from rachitis. What the result of this treatment proved to be is not stated; but in the discussion which followed the reading of M. D.'s report it was remarked that this injurious action of human milk had already been observed, in cases where young women had used puppies for "drawing the breast." The animals were observed under these circumstances to succumb speedily.—*Bull. Gén. de Thérap.* A. V. H.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JUNE 6, 1874.

EDITORIAL.

CREMATION.

THE question of the advisability of burning the dead is still everywhere the subject of active discussion, and the process appears to be growing in favor. In March of this year there were in Zurich two public meetings of about two thousand persons, for the consideration of the propriety of the adoption of cremation.

The speaker who opened the proceedings at these meetings called attention to the progress which the idea had already made in Switzerland, and stated that in several of the other cantons meetings had previously been held, and that in Bâle several orthodox clergymen had given the idea their approval, owing to the pressing need for all the room that could be made available in that small district. One of the medical professors of the High School then stated the danger to which Zurich especially was exposed. The cemeteries of that city are situated upon hills and cliffs under which lie the dwellings of the inhabitants, and from which the drainage enters into the springs at their base.

Measures were taken at the close of the meeting to form an association to discuss the question, and to ascertain the most suitable way in which a corpse could be burned. Numerous persons of varied social position became members of the society, which numbers over four hundred persons, and agreed that at their death their bodies should be burned. In this canton no opposition to this mode of disposal of the dead is looked for from the authorities. Similar associations

with the same object have been formed in other cities of Europe, in Berlin, Dresden, and quite lately in Vienna, and in the last-named city the authorities have directed an engineer to construct a furnace suitable for the purpose of burning the dead. In London, cremation appears to be a favorite theme with pulpit-orators, some favoring, some decrying it. In the same city a Cremation Society has been formed, and advertises in the *Athenæum*.

According to the *Medical Press and Circular*, a case of ante-mortem burial which occurred recently in France is about to become the subject of a judicial investigation, and will no doubt give a fresh impulse to the new movement. It is stated that about two years ago a young mother, shortly after the birth of her first child, was one evening seized with a fainting-fit, so severe as to be mistaken for death even by the physician, who, considering the great heat prevailing at the time, advised the inhumation of the body within six hours. This suggestion was unhappily adopted, but its frightful results only came to light the other day, when, the young widower having expressed his intention of marrying again, the mother of his dead wife claimed her daughter's body, intending to have it re-interred at Marseilles, where she resides. The vault was opened, and, to the grief and horror of all present, the coffin was found broken, and the corpse lying by its side, with hair and garments torn, and hands bitten through.

AS there are always persons ready to attach personal motives where they do not exist, and also to make personal applications where they are not meant, we want to state plainly that the Slowtown letters were admitted to our pages on the express understanding that they should not be personal attacks,—an understanding which, we think, has been carried out, at least so far as concerns the medical gentlemen connected with the canvass. The time seemed auspicious for calling attention to a source of grievous mischief, because the late very earnest, if not bitter, struggle had attracted general attention to it. The organization of our schools is to us about the worst conceivable: all the power being left in the hands of trustees,—self-elected,—representing nobody and responsible to nobody, having, moreover, themselves no direct interest in the schools, and being of very necessity ignorant of the wants of the profession and of the proper methods and aims of medical education. Is it a wonder that at least one trustee stated semi-publicly that one candidate was the best fitted for the place, but that he himself was going to vote for another on private

grounds? We may at some future day have more to say upon this subject, but the pressure on our columns renders present forbearance imperative.

CORRESPONDENCE.

NOTES OF TRANSACTIONS AT THE NEW YORK MEDICAL SOCIETIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—Among the matters of scientific medical interest recently occurring in our city may be mentioned the researches of certain gentlemen upon the cerebral centres.

Physiologists generally are aware that experimental researches have within a few years been made by Fritsch and Hitzig of Berlin, and Ferrier of London, with a view of proving the existence of, and of localizing, motor centres. Dr. George M. Beard, of this city, assisted by Dr. George B. Fowler, has also engaged in experiments upon the brains of living animals, having a threefold object in view,—namely, to ascertain how far the phenomena first observed by Hitzig and Fritsch, and subsequently by Ferrier, were demonstrable; 2, whether the objection of Dupuy and Canville to the conclusions derived from the German and English experimenters, on the ground that the current was diffused, was sound; 3, to push the inquiry still further, and by independent observation to settle, if possible, some of the questions suggested by the inquiry. The conclusions of Dr. Beard are—1. The living brain responds to electrical irritation, faradaic and galvanic. 2. There are in the brain certain different centres of motion, and probably of sensation. 3. The centres for the muscles of the mouth, neck, and legs appear to be in the anterior portions of the brain. The posterior portion is possibly the centre for special senses. Superficial irritation of the different parts of the cerebellum causes emprosthotonos; irritation of the tubercula quadrigemina causes opisthotonos; irritation of the hippocampi causes no visible reaction. 4. The brain in respect to these centres is symmetrical, and is indeed a double organ. 5. There is in the brain of a rabbit, in the posterior portion, about a quarter of an inch from the median line, a spot in each hemisphere that seems to be a centre for jumping and leaping movements.

Dr. Eugene Dupuy, before the Neurological and Electrological Society, May 18, conducted a series of examinations upon dogs and guinea-pigs, with a view to an examination of the theory of the existence and localization of motor centres in the cerebral hemispheres. The results of his experiments are embodied in the following conclusions. 1. That it is possible by exciting certain points of the cortical layer of the cerebrum to obtain contractions of every limb. 2. That as a rule the fore-limb of the opposite side is affected. 3. That the electric current must be propagated to the base of the cerebrum to excite either the nerves arising from it, or the

base itself, or the pons Varolii. 4. That if the dura mater be electrically excited contractions are obtained in the fore-leg, and generally in that of the opposite side. 5. The fact that the galvanoscopic frog is thrown into a state of contraction when its nerve touches some part of the cerebral mass far from the point excited, confirms the view that the electric current is propagated. 6. Contrary to the effects obtained by Ferrier, Dr. Dupuy has never been able to obtain effects upon the tongue, either of projection or retraction. 7. The whole cortical layer of the cerebrum is probably a centre of reflexion for a certain kind of sensibility capable of exerting a reflex action on motor or sensory nerves, but its preservation is not indispensable for the manifestation of voluntary or even intelligent action. 8. In the animals on which Dr. Dupuy has experimented, contractions of the opposite limbs can still be produced after the ablation of the optic and thalamic lobes and corpora striata of the side opposite to that to which the irritation has been applied. G.

NEW YORK, May 25th, 1874.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, APRIL 9, 1874.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

DR. CHARLES B. NANCREDE presented a specimen of *fatty tumor from the region of the scapula*, with photographs and microscopic slides, illustrating its structure, made by Dr. C. Seiler.

Dr. Nancrede read the following history and remarks: "The patient from whom this tumor was removed is a colored washerwoman, aged 37 years, who stated that she accidentally noticed the growth four years ago. It was then small, situated over the right scapula, just beneath the spinous process, was of slow growth, painless, and gave no inconvenience. During the past few months, however, its growth was quite rapid, with occasional stinging pains in the part, and considerable inconvenience caused by its extending down upon the posterior fold of the axilla. The patient had never received any injury to the part. I removed the tumor on the 19th of March, 1874, by the antiseptic method, in its entirety. In eleven days the patient was well, and, I believe that, had I had more faith in this method, the wound would have been soundly healed in half the time.

"I had determined to test the preservative influence of chloral on the first favorable opportunity, and accordingly placed the growth in a solution of about gr. xv of chloral to the ounce of water. It can be seen at a glance that beyond the ordinary maceration which any specimen must undergo in any fluid, there is no alteration or bleaching, for the small capillary vessels supplying the capsule can readily be seen. There is also no unpleasant odor. The microscopic preparations were taken after the growth had stood in the chloral solution some time. I think that most observers have been annoyed to find that after placing specimens in some one of the so-called preservative fluids they were useless for microscopic purposes. This objection evidently does not hold good with regard to chloral. The photographs taken by Dr. Seiler, aided by the specimens under the microscopes, show very beautifully the mode of growth of lipomata. The first

slide is a section of ordinary adipose tissue, and the extreme regularity in size of the component cells will be noted, with few or no interspaces at their angles. In the second, which is a section of the tumor, the great irregularity in size of the cells will be noticed, many being from one-fifth to one-fourth larger by actual measurement than those of normal adipose tissue, while many more are only one-quarter this size. In the third specimen,—mounted in Canada balsam, showing only the cell-walls,—in several places one of the smaller cells is seen situated between several larger ones, its walls much thicker, and studded at various points with masses of germinal matter. In many of the smaller interspaces will also be noted little masses of germinal matter stained deeply by the carmine solution, thus showing them to be newly formed. Owing to their great differences in size, the cells do not assume that comparatively regular pentagonal form seen in the first specimen, but tend to assume one more rounded. These appearances clearly indicate the mode of development of fatty tumors. In consequence of some irritation, there is set up a circumscribed proliferation of the connective tissue in some clusters of fat-cells. This is followed by a fatty infiltration of these newly-formed cells; and we thus have the explanation of the small cells arising between the large ones; for here at the angles the new germinal matter forms, which is gradually thinned out by the pressure of the fat within. This explains, too, the thicker walls of the smaller cells, which are younger, have less fat infiltrated into them, and therefore have their walls less stretched.

"I would now advert to the point of surgical interest in this case,—viz., the method of removal. I followed in its entirety Prof. Lister's method, but used, instead of his cere-cloth, Mr. Lund's antiseptic gauze. As this method has given rise to considerable discussion, and has been as heartily condemned as it has been praised, I will describe the steps. My instruments were all dipped in carbolized oil, made by adding one part of acid to nine parts of oil. The incision was made and the dressing completed under a spray of one part of the acid to forty parts of water, and the wound was closed with carbolized catgut ligatures and antiseptic adhesive plaster. Over the line of the incision several layers of linen steeped in the carbolized oil were laid, over this again the 'protective,' made by varnishing oiled silk on both sides and coating with starch, so that when dipped in the carbolized water some would be retained, and finally six or eight layers of the gauze and a pad of tow. On the third day the dressing was removed, and renewed under the carbolized spray, when most of the wound, which was between four and five inches long, was found to have healed by first intention. As I was a very lukewarm believer in this method, never having tried it, I left one angle of the wound open to allow drainage. Had I not done this, I think that I should have had union by first intention throughout the entire extent of the incision. During the time that the open part took to heal by granulation I do not think that there were twenty drops of pus discharged. Some of the catgut sutures I removed, others cut out, and one was partly absorbed, so that it came away as if the loop had been divided. Now, it is possible that I might have had this result by ordinary methods, but I certainly would have had more pus from the granulations, especially in a patient who warned me before the operation that former slight injuries had not healed readily. Nor is it likely that so large a wound, which from its position favored the collection of blood, pus, etc., would have healed in five days,—a result that I have no doubt I would have attained had I closed it entirely. I think, from the result of this case, and others in which I have adopted the method in part, that the reason it has so often proved unsuccessful is

because *all* the minutæ were not attended to. As to whether it is useful by excluding germs, as Mr. Lister originally thought, I do not pretend to know. Certainly the effects of exclusion of the air are well known, as in subcutaneous operations. The antiseptic method bids fair, in *some* way, to come nearer this than anything else that we know of at present."

The PRESIDENT remarked upon the apparently successful preservation of the color as well as the total absence of odor in the specimens thus preserved. The objection to all other preservatives, as chromic acid, bichromate of potassium, corrosive sublimate, and alcohol, lay in the fact that they either completely decolorized the specimen or added to it such intensity of color of their own that the original appearance could not be recognized. So, also, the shape was materially altered by these latter agents. There was less objection to solutions of arsenious acid on this score, though it possesses other objections in being deficiently preservative. He thought that the fact that chloral would permit the removal of specimens from the jars, and their examination, gave it extraordinary advantages.

Dr. R. M. BERTOLET said the objections to the use of this preservative fluid for preparations intended for microscopic study consisted in the fact that it did not harden the tissues placed in it.

Dr. JAMES TYSON had also used the chloral fluid for preserving specimens, and had recognized its deficiency in this respect. In other respects it answered well.

Dr. NANCREDE said that the sections exhibited of this tumor were hardened subsequent to their removal from the chloral fluid, and before the sections were made.

Dr. TYSON said that while the micro-photographs exhibited this evening were fair examples of their class, they presented the defects which he had always contended must attend attempts to photograph objects of any thickness whatever; that is, objects which required penetrating power and transitional focussing to bring out their points of structure. This could not be done, or at least had not yet been done with distinctness, in the micro-photograph. While he admitted, therefore, that photographs of very thin objects, as blood-corpuscles, might take the place of drawings with the camera, yet the latter, though immensely laborious, could alone supply the desideratum of an accurate picture when the object to be drawn presented any thickness.

Dr. F. P. HENRY presented a specimen of *cancer of the pylorus*, and read the following history: "The patient from whom this specimen of cancer of the pylorus was removed was an unmarried female, æt. 55, who had been under my care at different times for about four years. I first attended her in 1870, for rheumatism, from which she had suffered for more than twenty years. When I began to attend her she had been confined to her room for several years, being almost completely crippled by chronic rheumatism. All the joints had been affected, and the fingers were distorted so as to render them of little use. My efforts in the way of treatment were chiefly limited to relieving the acute exacerbations from which she frequently suffered, but, with the hope of achieving some more permanent success, and at the same time to remove the constipation, which was an important element in the case, I put her upon the use of Rochelle salts in drachm doses three times a day. Under this treatment she steadily improved, and in the summer of 1870 she descended the stairs for the first time in ten years. Whether this success was owing to the treatment or to the unusually warm weather of that year is of course an open question. This amelioration of the rheumatism was permanent. She remained free from any serious illness until I was called to attend her about the first of February of the present year. The symptoms at that time were

obstinate vomiting and constipation; but as she had been for a long time subject to transient attacks of acute indigestion, readily amenable to treatment, I at first anticipated nothing serious. The usual remedies not benefiting her, I began to suspect some organic trouble, and on palpating the abdomen I discovered a tumor about three inches to the right of and a little below the umbilicus, at about the junction of the umbilical and right lumbar regions. This tumor I proved to be disconnected from the liver by finding that there was tympanitic resonance on percussion between it and that viscus. It was hard, immovable, and somewhat tender. On pressure, pulsation was communicated to it from the abdominal aorta.

"As it was lower than we generally expect to find a tumor of the pylorus, the idea of a fecal tumor presented itself. The condition of the patient at that time was good: the pulse strong, and about 80. A pill containing two grains of aloes was administered three times a day, and on the third day operated freely three times, the discharges being fecal. The tumor was then examined, and no diminution in its size observed.

"Numerous remedies were employed to relieve the vomiting and nausea, among them the oxalate of cerium and the wine of ipecac in small doses,—the latter on the strength of Dr. Ringer's recommendation, in his work on Therapeutics. Neither of them was of the slightest service.

"The patient was seen by Dr. Howell, of Woodbury, N. J., in consultation, who, with Dr. Nancrede, was present at the autopsy. The stomach was found distended with fluid ingesta, and much below its normal position, the greater curvature descending more than an inch below the umbilicus. The pylorus was closed by a scirrhous thickening of its walls, but the resiliency of the tumor was so great that by using force the little finger could be forced through the duodenum. The thickening did not extend to the duodenum. The gall-bladder was distended with bile, and a large calculus could be felt through its walls. The microscopic examination made by Dr. Nancrede showed the characteristic fibrous alveoli of cancer crowded with large round cells. The specimen derives a further interest from the fact that it has been preserved nine days in a solution of hydrate of chloral, gr. xv ad 3i."

The PRESIDENT said that a point of unusual interest in connection with this case was the occurrence of carcinoma in a patient who had had rheumatoid arthritis. He did not remember ever to have met with the combination of carcinoma with this disease. He thought also that some writers on the subject of rheumatoid arthritis mentioned its tendency to exclude carcinoma.

Dr. W. G. PORTER presented, for Dr. J. G. ALLEN, a *calculus, bladder, ureters, and sacculated kidneys*, derived from a gentleman 76 years of age. Ten years ago, when in New York, he was suddenly seized with an attack of retention of urine, which was relieved by the catheter in the hands of an eminent surgeon of that city. The catheter was passed without difficulty, but the attack of retention was followed by cystitis, which laid him up for some time. Since then he frequently has had attacks of retention, and whenever an instrument was used for the relief of the patient, cystitis followed, although the catheter was always used carefully and by skilful hands. He thus acquired such a dread of all instrumental interference that of late years he would not allow a catheter to be used, and when he had retention he would go to bed and use opium suppositories until the urine began to dribble away. During all this time he suffered more or less from increased frequency of, or difficulty in, micturition; and finally died during one of the attacks of retention, with the bladder unrelieved.

Post-mortem.—On opening the abdominal cavity, the

distended bladder was found reaching about an inch and a half above the umbilicus, and uniformly adherent by its anterior surface to the abdominal wall. The adhesions were evidently not of recent formation; most of them were separated with some difficulty by the finger, some few bands requiring division with the knife. On opening the bladder, a large quantity of extremely ammoniacal urine escaped, and a calculus about the size of a walnut, weighing three drachms, was found; it was extremely rough and irregular on its surface, dark in color, and presented the appearance of what is known as a "mulberry calculus." The bladder was thickened, enlarged, and its interior surface was excessively ribbed. The prostate gland was very much hypertrophied, particularly its third lobe. The ureters were much enlarged and distended with urine. The left kidney was a mere membranous bag, containing urine, none of the secreting structure of the kidney apparently remaining. The right kidney contained a large cyst.

Dr. J. H. PACKARD asked whether there had ever been an attack of nephritic colic.

Dr. PORTER replied that the existence of stone had not been suspected.

The PRESIDENT said he hoped this specimen would elicit from the surgeons present some remarks as to the propriety of emptying the bladder by aspiration. He thought that, especially in consequence of the adhesions between the anterior wall of the bladder and the abdominal parietes, there would not have been any serious consequences in this case.

Dr. PORTER said that aspiration had been suggested in this case, but not tried. He had had experience in one case in which he had aspirated the bladder during his last term of service at the Presbyterian Hospital. The man had a very tight stricture, in which he could introduce no instrument, and after failing to catheterize he aspirated the bladder above the pubes. On the first occasion the relief was so great that the patient went to sleep during the operation. It was followed by no bad symptoms, and he was removed to the hospital the next day. After again failing to introduce the catheter during etherization, he again aspirated, with like good results. The next day, under the use of opium suppositories, the urine began to dribble away, and the man was so relieved that he eloped from the house, and had not been heard of since.

Dr. PACKARD said that he had had no personal experience with aspiration for the relief of retention of urine, but thought there was abundant testimony to its value, such as that given by Dr. Porter. He would like to ask whether the fact that catheterization, even performed with the greatest skill and care, was invariably followed by severe cystitis, would not have justified the suspicion of vesical calculus, in addition to the prostatic enlargement. It might seem as if a stone of any size would be apt to be detected accidentally, by the catheter striking it; but this would readily be prevented by the stone lying in the bas-fond of the bladder, behind the swollen prostate.

Dr. JOHN ASHHURST, JR., said that he had no personal experience in the use of the aspirator in cases of retention of urine, but believed its employment under such circumstances to be both safe and effectual. He should not, however, be disposed to resort to aspiration in any case in which, as in the present instance, catheterization could be readily effected. He did not think that the frequent recurrence of cystitis would necessarily lead to the suspicion that a calculus was present, for in cases of enlarged prostate, such as this, the bladder was seldom entirely emptied, and a condition of chronic cystitis, with vesical catarrh, was commonly set up,—a condition which would readily be converted into one of acute cystitis by very slight causes. Dr. Ashhurst

hoped that the stone found in this case would be submitted to careful examination; for, while its general appearance was that of a mulberry calculus, one of the phosphatic variety would be more naturally looked for in a case of urinary retention from prostatic enlargement. If, as was probably the case, the stone contained both phosphates and oxalate of lime, it would be interesting to know the proportions in which its several constituents were present.

Dr. PACKARD said that in the first volume of the Society's Transactions would be found a drawing of a stone of this character. The specimen was presented by Dr. J. Darrach, now of Germantown.

The stone was referred for analysis to a special committee consisting of Drs. Porter, Isaac Norris, and Hare, who reported May 28, 1874, as follows:

"The committee to whom was referred the chemical nature of the calculus exhibited at a stated meeting of the Society, would report that it is of the variety known as the mulberry calculus, and consists principally of calcium oxalate. Externally it presents the usual warty character, stained with blood, and is exceedingly hard. Before the blowpipe it is converted into a carbonate, and finally into lime. It dissolves in hydrogen chloride aided by heat, and more readily in hydrogen nitrate, and gives with the spectroscope the characteristic orange and green lines with the purple band in the more refrangible part, and with the liquid tests the usual reactions for a calcium salt. The presence of oxalic acid is also shown when boiled with potassium carbonate and the whole neutralized with an acid and a soluble lime salt added. All of which is respectfully submitted, and the committee ask to be discharged. Dr. Hare concurs in the above."

Dr. J. H. PACKARD presented the *viscera* obtained from the *autopsy* in the case of Mrs. T., who died four weeks after an amputation of the breast for cancer, the wound being almost completely healed. The death was preceded by about half an hour of increasing dyspnoea, she having been previously in perfect health in this respect.

Heart fatty; valves normal; aorta entirely free from atheromatous deposits. The heart was full of liquid blood, as were also the aorta, vena cava, and blood-vessel system generally.

The pulmonary arteries were full of firm clot; that in the right branch being firmer, and occluding the vessel more completely, than that in the left. On the right side the clot was traced through several successive ramifications of the vessel into the middle lobe of the lung. On the left side it was less extensive, and tended towards the lower lobe of the lung.

Lungs everywhere crepitant; perhaps somewhat emphysematous in the lower lobes. Old cicatrices existed at both apices, and in the left lung there was a very small hardened tuberculous deposit.

The bronchial glands were much enlarged, and full of carbonaceous matter.

Liver in a very early stage of cirrhosis. *Gall-bladder* much thickened, and lobulated (or contorted?); quite white.

Pancreas irregularly thickened,—in some places hardened, and in others so soft as to tear readily.

Spleen quite diffuent; a thick sheet of white lymph over its anterior surface.

Left kidney and suprarenal capsule normal; right not examined.

The seat of the operation-wound was found almost entirely healed, and the neighboring tissues perfectly sound, and free from appearance of disease.

The explanation of the fatal result in this case seemed to be that, from some trifling exertion, the weak and fatty heart "slowed" its movements, when coagulation began to take place, especially, or perhaps only, in the

pulmonary artery, where the current was less forcible than in the aorta. The slight obstruction thus produced would still further embarrass the feeble right ventricle, and this circumstance would favor the closer blocking of the vessels. Hence, violent respiratory efforts would ensue, the blood not having access to the aerating organs, and death was the result of mechanical asphyxia.

Dr. PACKARD called attention to the fact that in this patient, the subject of cancer, there were evidences of the former occurrence of tuberculous deposit in the cicatrices at the top of each lung.

The viscera were referred to the Committee on Morbid Growths for further examination, who reported May 7, 1874, as follows:

"Your committee found in Dr. Packard's specimen a large-sized gall-stone impacted in the ductus choledochus, where it had caused the lining membrane to ulcerate. The portion of the tube lying in front of the foreign body was pervious, although its mucous membrane was very much swollen and congested. The gall-bladder itself was contracted, and contained a small quantity of thick, dark, grumous bile; its walls were covered with a layer of fat half an inch in thickness. The head of the pancreas was found very much indurated, and somewhat increased in size. This was found upon examination to be due to an excessive development of connective tissue between the normal secreting parenchyma."

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, MARCH 25, 1874.

THE PRESIDENT, DR. JOHN SWINBURNE, in the chair.

THE name of Dr. C. S. Merrill was proposed for membership, and referred to the appropriate committee.

Dr. ISAAC DE ZOUCHÉ read an elaborate paper on the subject of Hygiene in Relation to Hospitals. [We have space for only a few of his points.] In appropriating an old building for hospital purposes, or commencing a new one, the question of the greatest importance is that thorough drainage and sewerage be provided for at any cost. A soil saturated with moisture, even though it be from pure water, is a fruitful source of fever. If such is the result from the presence of moisture from pure water, how much more fatal the results when sewerage is allowed to collect about foundations, tainting the air and poisoning the water,—as it were, offering a premium to the angel of death to abide there!

In constructing a new hospital there would seem to be no excuse for overlooking such vital points, and yet the German Hospital in New York was built on a site which included an old drainage-stream. Malarial poison from this source so universally affected the patients that it was in serious contemplation by its trustees at one time to abandon its use for hospital purposes. So universal was the fact that patients entering it contracted malarious disease, that it became the ordinary practice to administer quinine to its inmates as a prophylactic immediately upon their admission.

Blood-poisoning is another form of the various manifestations of defective ventilation.

The walls and ceilings may be whitewashed a dozen times a year, and you may spend a fortune in the use of disinfectants, but the fact will force itself on you that every year, notwithstanding the great advance made in surgery proper, the proportion of fatal cases does not grow smaller, but the reverse.

The remedy seems to lie in the establishment of hospitals beyond city limits, where a large amount of space may be secured at comparatively small cost.

The building should be only one story high, with ventilation amply provided for at the apex of the roof; undoubtedly the pavilion-plan is the best. Such a plan has been carried out at Leipsic, as I learn by an admirable article in the *New York Evening Post* of March 23. At the gates of Leipsic there is an immense shed-hospital consisting of fourteen large "sheds," if such a name can be given to what are really handsome pavilions. They are detached, one-story, substantial frame buildings, filled in with brick, connected through an ante-chamber by a gallery, and facing a garden. They are one hundred feet by thirty-two feet in size inside, with a height of fifteen feet to the eaves and of twenty feet to the roof-ridge.

They stand sixty feet apart, are raised on stone piers four feet higher for the sake of ventilation. There are also ridge-ventilators, with movable sashes to furnish protection from cold during a part of the day in winter. Each "shed" has twenty-four beds, with nurses' room, baths, kitchen, and closets complete. There are isolated sheds for contagious diseases. No lying-in women are admitted. During twelve months, from August, 1872, to 1873, Professor Wiersch, who has direction of the surgical clinic, performed two hundred and sixty-six serious operations and did not lose a case from pyæmia, while prior to the construction of the pavilions, in the old stone hospital, which is now the central building, he lost from forty to fifty amputations from this cause annually.

The more space for free circulation of air our hospitals can secure, the nearer we can come to the Leipsic model, the better will be the economical and sanitary results.

Dr. D. T. CROTHEN then read an elaborate paper on Inebriation, its Pathology and Treatment.

[This is also crowded out of our columns.]

REVIEWS AND BOOK NOTICES.

OUTLINES OF COMPARATIVE ANATOMY AND MEDICAL ZOOLOGY. By HARRISON ALLEN, M.D. Second Edition. J. B. Lippincott & Co.

The success of this brochure of Prof. Allen is a very favorable indication of a growth in desire for abstract science somewhere in America; unless, indeed, as may have been the case, the book has sold largely abroad. These outlines bear about the same relation to an expanded work upon the subject, that pemmican does to good beef,—everything there, but everything reduced to the lowest state of condensation and dryness; the strength preserved, but the attractiveness to the palate reduced to a minimum. The book would have been a perfect godsend to the redoubtable Gradgrind, for, excepting the dictionaries, there are more facts in it than in any other book near its size we know of in the language. In the space of one hundred and thirty-six pages of not very fine print is contained almost everything about comparative anatomy worth knowing. To those coaching for an examination, the book, it seems to us, would be invaluable; and we can also highly commend it to any one who wants a brief but succinct and a cheap but satisfying work of reference upon the subject of which it treats.

M. PANAS has used solutions of "chloride of lime," or chlorinated water, very successfully in the treatment of varicose ulcers. The solution is applied on lint, and renewed frequently until healthy action is set up, when epidemic transplantation may appropriately be performed to hasten cicatrization.

GLEANINGS FROM OUR EXCHANGES.

DOUBLE DIAPHRAGMATIC RUPTURE AND HERNIA (*New York Medical Journal*, April, 1874).—Dr. John M. Woodworth reports the case of a man who was suddenly attacked with severe pain of a colicky nature, in the region of the umbilicus, exacerbating at intervals. His pulse was slightly accelerated; there was no vomiting; two grains of quinia with one-fourth grain of morphia gave immediate relief. On the evening of the same day his symptoms were those of an acute attack of pleurisy; sharp pain located in the left side about the eighth rib, impaired respiration, little cough, full, rapid pulse, and moist skin. He was given morphia hypodermically, and a mixture of calomel, jalap, and Dover's powder. The next day he felt better, took some Rochelle salts and castor oil, and had a copious discharge from the bowels. The following day the pain still remained; there was dullness on percussion over the whole left chest, with the exception of the seat of pain, which was resonant. The day after, he was suddenly seized with nausea, vomited slightly for the first time, and then lay down and died.

At the post-mortem examination, there was found a double hernia of the intestine and omentum, through a double rupture of the diaphragm to the left of the œsophageal opening. The left lung was completely collapsed; sections from it would not float. Ten days previous to his death, he had been engaged in pushing heavy planks up a steep gangway, having their weight full against his abdomen. He had felt a sudden snap inside, and had then felt faint, but had soon gone to work again.

THE TREATMENT OF SYPHILIS (*The Lancet*, April 25, 1874).—Dr. Spender has arrived at the following conclusions from his experience in the treatment of syphilis.

1. In the second or exanthematous stage of syphilis, it is almost always useful to administer mercury and iodide of potassium simultaneously. Ten grains of the iodide, with a grain and a half of gray powder or blue pill, should be given three times a day.

2. The "intermediary squamous syphilides" are best treated with perchloride of mercury, which should be given in compound tincture of cinchona.

3. The early tertiary symptoms of syphilis are often strikingly relieved by the soluble iodide of mercury, or rather by that double compound of iodine and mercury, which is formed by adding iodide of potassium to a solution of perchloride of mercury. It is impossible to praise too highly the therapeutic qualities of this medicine.

CURES FOR THE OPIUM-HABIT (*The Peninsular Journal of Medicine*, April, 1874).—Professor Albert B. Prescott, of the University of Michigan, has examined three of the various articles advertised as infallible cures for the opium-habit. The first was a pink liquid containing meconic acid and narcotina, but no morphia, and was therefore essentially opium with the morphia taken out. The second and third were colored and flavored solutions of sulphate of morphia, on which the proprietors made immense profits.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 26 TO JUNE 1, 1874, INCLUSIVE.

SURGEON JOHN MOORE, and ASSISTANT-SURGEONS J. J. WOODWARD and J. S. BILLINGS, directed to attend the Annual Meeting of the American Medical Association at Detroit, Michigan, on June 2, and on its adjournment rejoin their proper stations. S. O. 118, A. G. O., May 28, 1874.

SATURDAY, JUNE 13, 1874.

AMERICAN MEDICAL ASSOCIATION.

WE are indebted to Dr. William B. Atkinson, Permanent Secretary, for copies of the *Detroit Free Press* containing a semi-official report of the American Medical Association, and offer our readers the following epitome.

FIRST DAY.

The Association met June 2, at Hough's Theatre, Detroit, at half-past eleven, Dr. I. M. Toner, President, being in the chair. After the opening prayer by Bishop McCoskry, Dr. William Brodie made a very neat speech of welcome, in which, *inter alia*, he stated that when the Association first honored Detroit with its presence, eighteen years previously, the city numbered only forty thousand inhabitants; but now it boasts of a population of one hundred thousand, of a city hall that cost \$600,000, and of a system of sewage so complete and so supplemented by other hygienic appliances and regulations that the mortality of the city in 1873 was only two and a half per cent.

After the completion of this address and the announcement of the programme by Dr. Brodie, Chairman of the Committee of Arrangements, the question of disputed seats raised in regard to several delegates was referred to the Judicial Council, and, on motion of Dr. Brodie, a number of members of the profession from Canada were unanimously invited to take places on the floor. President Toner then delivered his address, which contains much that is of interest, but is scarcely fitted for abstraction. We have failed to perceive any especial central idea in it, unless it be that of the necessity of progress, of the need of a first-class endowed physiological and pathological laboratory somewhere in the country, and of the general interest which the profession ought to feel in fostering original work.

Section One.—Practice of Medicine, Materia Medica, and Physiology. Dr. Bulkley, of New York, read a paper on "The Management of Eczema," in which he treated at considerable length the various forms of local and constitutional cutaneous diseases. Among the remedies applied by him in his practice, with varied failures and successes, were arsenic, glycerin, cod-liver oil, tar-oilment, mutton-suet and lard, carbolic acid, and a solution of tar, water, and caustic potash.

In reply to a question, Dr. Bulkley stated that he had administered a one-grain pill of carbolic acid before breakfast, gradually increased to four or five grains daily. He had not used carbolate of iron.

Dr. Farnsworth, of Iowa, then read a long paper on "Ammonia," most of which is only of interest, first, as showing how much easier it is to speculate and reason than to work out new facts in the laboratory; secondly, as revealing of how little permanent value work of the former kind is when done. Although ammonia is in so frequent use, we have almost no positive knowledge as to its action, and Dr. Farnsworth's paper throws no light on the subject.

The clinical portion of Dr. Farnsworth's paper is of more interest, although containing little of real novelty. We extract the following from it:

"In a case where respiration was suspended during the administration of chloroform, I injected three drops of aqua ammoniæ, diluted with water, into the subcutaneous tissue of the arm. The patient rallied at once, and complete recovery took place. In a case of bronchitis in a debilitated patient, an opiate had been incautiously given; the secretions were suspended, and asphyxia seemed imminent. Five drops of aqua am-

moniæ, diluted with a drachm of water, were injected under the skin. The effect was immediate. The circulation was aroused, a large quantity of mucus was discharged from the lungs, and the arterial color of the circulation restored. The patient recovered under the continued administration of carbonate of ammonium and the alcoholic stimulants. In two other cases of bronchial obstruction I have used hypodermic injection of ammonia with marked success.

"I was called, at four o'clock in the morning, to see a man who was laboring under symptoms of opium-poisoning. I found, upon inquiry, that he had taken somewhat over an ounce of tinct. opii at 10 P.M., by mistake for port wine. The extremities were cold, respirations from four to six per minute, pulse full, lips livid; was unable to rouse him to consciousness. Injected into his arm three drops of aqua ammoniæ. It increased the respirations and improved the color of the circulation. A second injection was given, other means of resuscitation were used, and the patient gradually recovered. In a case of shock from railroad injuries, with the pulse hardly perceptible, the stomach would retain nothing. Inhalations of chloroform were alternated with those of ammonia. The patient very soon came under the anæsthetic, and the crushed leg was removed. Reaction occurred very soon, and the patient made a good recovery.

"In the catarrhal bronchitis of children I have used inhalations of ammonia with good results."

After the reading of the paper, a vote of thanks to Dr. Farnsworth, and the reference of his article to the medical periodicals for publication, the section adjourned.

Section Two.—Obstetrics. There does not appear to have been anything of much interest before this section.

Section Three.—Surgery and Anatomy.

Dr. Dunlap read a well-written report of a case of *Enchondroma over the Sternum*, which it hardly seems necessary to reproduce here.

Dr. E. M. Moore then read a paper on the *Epiphyseal Fracture of the Humerus*, of which, and the subsequent debate, the following is an abstract.

Professor R. W. Smith has stated that separation of the humerus at the line of junction of upper epiphysis and shaft is not uncommon in early life. The head of the bone can be distinctly felt in the glenoid cavity; a slight depression is felt beneath it, the head remaining motionless when the shaft is rotated. A striking and abrupt projection is observed beneath the coracoid process, caused by the upper extremity of the shaft being drawn inward by muscular action. The shaft seldom clears the head, and hence the small amount of shortening. This projection is smooth and slightly convex in contrast to the irregular margin of ordinary fracture. The elbow projects but little from the side, and can be readily brought in contact with it. Pressing the upper end outward while holding the elbow to the side and making extension and counter-extension, the deformity disappears, to recur as soon as left to unopposed muscular action.

Diagnostic points are, first, the projection beneath the coracoid, and second, the immediate recurrence of the deformity when the means for reduction cease retaining the shaft in place, there being no fracture of the superior end of the humerus in which retention is so difficult. In general the true nature of the injury is unrecognized, although the symptoms have been clearly stated by Sir A. Cooper and Professors R. W. Smith and Frank H. Hamilton. This arises from no accurate conception of the change of position having been put forth, and no method securing precise retention having been proposed, in so far as he (Dr. Moore) was aware.

The symptoms of this fracture are striking and uniform. The shaft of the humerus is so inclined as to carry the elbow a little backward and outward, while the superior end of the shaft is brought forward so as to make a prominence less rounded than the head, and lower down. It is usually found an inch and a half (at the age of 12 or 14) below the acromion, and near the coracoid process. The curved line from the acromion down to the projection has a long sweep instead of the small sphere of the natural head. This appearance is pathognomonic, and may be safely trusted in diagnosis without insisting upon crepitus. As in other epiphyseal fractures, this is not clear and sharp, as when the fracture is of bone, but is muffled. When the arm is moved gently and without grasping the head, the peculiar lock of the surface is sufficient to cause the head to rotate, and thus the timid practitioner fails in getting his pathognomonic sign; but if the head be firmly grasped it can not only be felt in the glenoid cavity, but held sufficiently firm to get this muffled crepitus by rotating the humerus or by carrying the elbow inward, and thus rubbing the two surfaces on each other. In addition to these striking symptoms, we may add a shortening of half an inch or a little more. When the two shoulders are inspected from behind, the impression given is that of luxation; for there is a slight flattening of the shoulder produced by drawing the fibres of the deltoid a little forward. The breadth of the shoulder is also increased when seen in profile. The motions of the arm are somewhat circumscribed: the ability to carry it upward and forward as well as upward and outward is impossible much beyond a right angle with the body, but affects the rolling of the scapula so that the hand can be placed on the head.

Reduction is effected by carrying the arm forward and upward to the perpendicular line. Retention is effected by moderate extension while bringing the arm down by the side, maintaining this slight extension until dressings for the purpose of continuing it are applied. Swinburne's method fulfils the indications easily and perfectly.

Even if not restored, the arm soon becomes useful, and nature gradually rounds off the prominence of the diaphysis and elongates the capsule at the lower border, allowing the motion upward to improve.

Case 1.—John Duff, aged 14, fell, striking on the right shoulder. Seen two hours after by a well-instructed physician, who considered it a dislocation. Violent traction was made by two men, but when the extension ceased the deformity reappeared, although the supposed dislocation was supposed reduced. Next day sent to Dr. Moore. The bandage was worn four weeks. The restoration is absolutely perfect.

Case 2.—Nellie C., aged 16, fell from a tree, striking the front of the shoulder. Was seen by family physician, who recognized no displacement. Fourteen days later was seen by another of great eminence, with like result. A third thought there was luxation. He (Dr. M.) saw the patient seventeen days after the accident. After reduction, applied Swinburne's dressing, which was worn about two weeks. A year afterwards the result was found quite perfect.

Case 3.—Charles B., aged 6, fell on his shoulder. A physician, having diagnosed luxation, put him under ether, but found motion perfect without crepitus, and supposed the deformity resulted from ecchymosis. Dr. Moore saw him at the end of two weeks, when the deformity was more marked, the swelling having subsided. The boy was the subject of infantile paralysis during his second year. The shrunk muscles allowed of almost absolute demonstration. Adhesions broken up under ether, when the muffled crepitus was plain. Restoration reported perfect three months afterwards.

Case 4.—Michael M., aged 18, fell, injuring his left

shoulder. A physician supposed that a dislocation had occurred. Four days later, Dr. Little, of New York, observed the projection under the coracoid, but found scarcely any shortening. Under ether, slight extension removed it. Failed to reduce deformity. Dr. L. took the patient to Dr. Moore. Adhesions broken up under ether, and reduction effected. Three months after injury, the movement of the joint was perfect, except that he could not raise it so high as the other, but was still improving.

Dr. Moore had reduced two cases at the end of two weeks, but did not know whether it would be possible at the end of four. If adhesion had occurred, break it up if possible.

Dr. Hughes could not understand how this fracture was to be distinguished from fracture of the anatomical neck. Fracture at the epiphyseal line will give the symptoms, it is true, but, considering the attachment of the supra-spinatus, infra-spinatus, and teres minor muscles with the action of the biceps, he would expect the symptoms in fracture of the anatomical, and perhaps too of the surgical, neck. He had known a fracture of the surgical neck occurring four months before to be mistaken for dislocation. He doubted if reduction and retention could be effected with the ease asserted.

Dr. Keller explained that fracture at the epiphyseal line does not occur except during childhood and adolescence. He believed the method of reducing it to be original with Dr. Moore.

Dr. Robert Reyburn, of Washington, doubted the separation of the epiphysis so late as the age of nineteen, as mentioned by Dr. Moore as having occurred in a case of Dr. Hamilton's. The treatment of injuries at this part is difficult. Fractures of the anatomical neck should be capable of like treatment. He supposed fracture of the anatomical neck is what had really occurred, instead of at the epiphyseal line as supposed.

Dr. Moore explained that epiphyseal fracture could only occur before ossification has occurred, the age for which differs. From Sir A. Cooper's and R. W. Smith's report, he had supposed sixteen to be the limit of age, but Hamilton's case gives the symptoms at nineteen. Ossification may not be complete until the twenty-fifth year. During adolescence the epiphyseal line is the weakest place, and hence fracture is more likely to occur there. During this age suspect epiphyseal fracture. This fracture is not like any other, because it has a specific and definite line, while other fractures have an indefinite line through the anatomical or the surgical neck, or through the tubercles.

Dr. Hughes asked why this fracture is so liable to be mistaken for fracture of either neck.

Dr. Moore replied that when the bones are brought into place they are held there by the action and pressure of the muscles. The head rolls around, but does not produce the pathognomonic crepitus,—at best getting only a muffled crepitus. Again, we have mobility, not found in dislocations. The error in diagnosis occurs because the profession do not know what to make of it. The error should not be made, because of the prominent projection, and because the forces acting upon the fragments are uniform. We do not have this projection in fracture of either anatomical or surgical neck.

Dr. Atlee, of Philadelphia, asked the opinion of the chairman, Dr. Gross, who stated in reply his entire concurrence in all Dr. Moore had said.

Dr. Gregory, of St. Louis, asked whether necrosis of the articulation had occurred in a case mentioned which had been examined six months after, to which Dr. Moore replied in the negative.

SAYRE ON FRACTURES.

Dr. Lewis A. Sayre, of New York City, had been appointed to make a report on fractures, two years ago,

but was prevented by illness. He presented statistics taken from Bellevue Hospital, prepared by House-Surgeon Van Wagner. He had lately learned of actual cases really treated by what he had supposed to be the obsolete method of waiting nine days for the swelling of the soft parts to subside. Again, most authorities on fracture stated that in fractures of the long bones, particularly if oblique, we were to expect deformity. Some say it is quite impossible without it. He thought this wrong, and the sooner corrected the better. Statistics proving shortening should only be saved to be disentombed to assist in defeating suits for malpractice. The long bones keep the body in place. Fracture occurring, the muscles contract and produce distortion of the vessels and nerves, the ends of the fragments causing irritation and inflammation. All that is necessary in any fracture is extension and counter-extension in the right direction, so as to have accurate adjustment.

Again, a fracture should be reduced as soon as you reach it. In all long bones it can be done with ease by extension and counter-extension. There was no vacuum in the thigh, for example, and if the femur was removed it would leave the mould of its form there if sufficient extension and counter-extension were made with perfect accuracy of adjustment. He illustrated by a very simple apparatus of wood and india-rubber cords the operation of the muscles upon the fractured bones. This idea he had got from Dr. Swinburne, of Albany.

If extension greater than normal be made, it would cause reflex contraction and irritation; but if only enough for adjustment, all was quiescent. After adjusting it we may have just enough fixation for accurate retention. Again, we must not wait for the subsidence of the swelling of the soft parts. Gutta-percha, as a means of retention, should be done away with, because of the foul odor produced, but we might use starch bandage, plaster of Paris, or leather. In compound and complicated fractures the principle is the same,—even in the extreme case of severe mangling from railroad injury. With perfect adjustment we have no pain. We can also send them into the open air. If the treatment be fairly applied, we have no shortening. In point of fact, it should be longer by the thickness of the matter between the ends of the fragments. Of one hundred and fifteen cases treated in Bellevue, some are longer, some without shortening. Many have the sixteenth or the eighth of an inch shortening. Excluding three cases, one of which had two inches, the second one and three-quarters, the third one and a half, these cases suffering respectively from abscess, delirium tremens, and pneumonia, and, being kept horizontal, had permitted shrinkage and hence shortening—excluding these, a very highly favorable average had been obtained.

Dr. Hodgen, of Missouri, objected that if a thigh be placed in the plaster of Paris splint in the straight posture, the muscles on the back of the thigh will be tense and those in front lax. We cannot bring *all* the muscles to a state of normal extension at the same time, and hence a position in which there should be no reflex irritation would be marvellous. In general, spasmodic contraction would occur. Dr. Sayre has said it does not matter what means are taken, so we succeed. But what means are we to use? Again, he says, do not make it too long! Now, the calcareous matter at the end of the fragments would soften and tend to produce shortening. If a fracture be oblique, something more than plaster of Paris is needed; otherwise, not.

Dr. Sayre stated that he had said that extension and counter-extension should be made in the proper direction, and then on no side would any muscle be stretched. All he had claimed was that it was better to start out with the idea that we could secure perfect results rather than that we must necessarily have shortening. In fracture of the femur we are to have the

thigh-piece capable of being lengthened or shortened if treated upon the inclined plane. This was first accidentally ascertained by Dr. Nelson, of Lower Canada, where a lumberman had both thighs broken, and by chance had got upon a ledge of rock whose width was precisely the length of the thigh,—such being the relief of pain that the man had fallen asleep. Taking the hint, he made an inclined plane to suit the thigh, and had a perfect result at the end of two months. Dr. Nelson was then sued for the alleged malpractice of keeping his patient unnecessarily confined, and had to flee his country.

Dr. Gregory, of St. Louis, expressed his astonishment. He thought Dr. Sayre's results barely possible, and wanted further evidence. He treated his cases by extension and counter-extension, with all the perfection of adjustment possible with mechanical appliances. If he had seen fractures occur without shortening, he had forgotten it. He had seen young persons get well without shortening of the limb as a whole. We all know that we cannot get union of bones or soft parts without previous softening. There is necessarily some loss of material where there is inflammatory action. Inflammation always consumes some of the soft parts. A young person's getting no shortening might be accounted for by irritation; but he did not think an adult could get union without shortening. Again, precise adjustment was practically impossible: the reverse was all talk and might do to tell *students*. The new material used in repair *will contract*, even if the injury be the simplest cut in the finger. If fractured limbs are as long, it is to be accounted for by growth somewhere else. Plaster of Paris has the advantage of allowing patients to go about, but he thought the best results as regards proper length would be obtained by the use of extension and counter-extension. He thought plaster of Paris just as suitable in treating injury of the soft parts as of bones.

At this point in the discussion Dr. Brodie entered the room, and announced that the Mayor was in his room, waiting to receive the delegates.

On motion, the further discussion of this subject was made the special order for Wednesday.

The section then adjourned until Wednesday at 2.30 P.M.

Section Four, Medical Jurisprudence, met only to adjourn.

Section Five, Public Hygiene, was engaged in a long discussion upon the propriety of petitioning Congress to establish a national health bureau, and finally decided in the affirmative, and also adopted the following resolution:

"*Resolved*, That, with a view to the establishment of a national sanitary bureau, it is expedient, at the present time, to press, through State medical societies and physicians everywhere, upon the legislatures of the several States, the importance of establishing State boards of health."

SECOND DAY.

The meeting was called at the Opera-House at 9.30 A.M. After the announcement of the Committee on Nomination, and the election of permanent members, several resolutions of no general interest were acted upon.

Dr. N. S. Davis then read the report of the Judicial Council. The report was adopted on the motion of Dr. Vandeman, of Tennessee. It stated that letters had been addressed to thirty or forty persons in different parts of the country, and of these only five expressed a decided dissatisfaction with the present code, whilst fourteen were positively opposed to the slightest alteration; an evidence that the great majority of the profession are satisfied with the code as it is.

After a careful examination of the code, the Council is of the opinion that it expresses the ethical relations and duties of the profession as completely and concisely as possible.

In regard to specialties, the Council report is *verbatim* as follows:

"Then the code of ethics very properly makes no mention of specialties or specialists, but presents plainly the rules necessary for the maintenance of professional character as applicable to all. But we are asked, How, then, can those who wish to pursue a special practice make known their position to their brethren and the public? We answer that the title of Doctor of Medicine covers the whole field of practice, and whoever is entitled to that appellation has the right to occupy the *whole* or any part of the field, as he pleases. The acceptance of this honorable title is presumptive evidence to the community that the man accepting it is ready to attend practically to any and all duties which it implies. As all special practice is simply a self-imposed limitation of the duties implied in the general title of doctor, it should be indicated, not by special or qualifying titles, such as *oculist*, *gynecologist*, etc., nor by any positive setting forth of special qualifications, but by a simple, honest notice appended to the ordinary card of the general practitioner, saying, 'Practice limited to diseases of the eye and ear,' or 'to diseases peculiar to women,' or 'to midwifery exclusively,' as the case may be. Such a simple notice of limitation, if truthfully made, would involve no other principle than the notice of the general practitioner that he limits his attention to professional business within certain hours of the day. Neither could it be regarded as a claim to special or superior qualifications. To give the specialist any privilege beyond this would be to invest him with a special privilege inconsistent with the equality of rights and duties pertaining to the whole profession. We see no reason, therefore, for recommending any change in the present code of ethics in reference to this subject."

In regard to doctors bidding against one another for public services, the report says:

"The present code of ethics, while sanctioning a most liberal bestowal of gratuitous professional service to the poor, whether as individuals or in public charitable institutions, and in aid of the sanitary interests of the communities, yet expressly prohibits the bestowal of such services on well-to-do individuals, endowed, mutual benefit, or any kind of money-making institutions, societies, or corporations. It also expressly prohibits all attempts to attract attention and make merchandise of charity by ostentatiously parading before the public notices proffering services and medicine to the 'poor gratis.' We see no reason why this is not sufficient so far as relates to the regulation of gratuitous services. To govern the matter of compensation the code simply gives us the following general declaration: 'Some general rules should be adopted by the *faculty*, in every town or district, relative to *pecuniary acknowledgments* from their patients; and it should be deemed a point of honor to adhere to these rules with as much uniformity as varying circumstances will admit.' The aim appears to have been to allow sufficient variations in the rate of compensation to accommodate the varying habits and circumstances of different communities, and yet to bind each individual to an honorable compliance with the general rules established by his professional brethren. Such being the correct ethical principle, the difficulty consists in tracing and maintaining clearly its practical application. That the principle laid down in the paragraph just quoted is inconsistent with all contracts or agreements to attend individuals, families, companies, corporations, or any associations or institutions other than those of a strictly charitable character, for a speci-

fied sum per month or year, without regard to the amount of medical services that might be required in the time specified, no one can reasonably doubt. It seems to us equally inconsistent with the ethical rule to enter into a contract with a manufacturing company to attend their employés, or with a school to attend its patrons or scholars, for a fixed sum per annum, to be derived from the levy of a certain percentage on the wages of the employés or on the tuition-fees of the students; for, however plausible may be the humanitarian idea of securing for the employé and the student adequate medical attendance when sick at the smallest average cost, the practical working of the system violates both the rule that compensation for medical services should be in accordance with the kind and amount of services rendered, and that every individual and family should be free to choose their own medical attendant without dictation or indirect restraint.

"These observations do not apply to a certain kind of contract-service sometimes required in connection with the medical staffs of the army and navy, nor to the hospital-tax on sailors in the marine hospital system, for reasons too obvious to require mention. One other subject requires a few moments' attention. There is a class of public charitable institutions, such as county almshouses, orphan asylums, etc., supported by public taxation. In many of the States the public authorities having control of such institutions have annually asked for bids from the profession, offering to award the contract for professional services to the one who should bid for the lowest pecuniary considerations.

"While as charitable institutions any member of the profession might offer his services to such of the poor inmates as might ask for them gratuitously, yet the idea of asking members of the profession to bid against each other for the pay for public professional services is repugnant to every feeling of professional honor, and often productive of great injustice to the sick poor.

"The public authorities in all such cases should fix such just rate of compensation for the necessary medical services as they may deem best, and then appoint the best medical man who is willing to accept the compensation proposed. And we have no doubt but that a proper attention to this subject on the part of the profession would secure the necessary change."

The amendments of the plan of organization next came up. After considerable discussion, the following amendment was adopted:

Strike out the second paragraph of Article II., and insert the following:

"The delegates shall receive their appointment from permanently organized State medical societies, and such County and District medical societies as are recognized by representation in their respective State societies, and from the medical department of the army and navy of the United States."

Also, strike out the fourth paragraph of same article, and insert:

"Each State, County, and District medical society, entitled to representation, shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number. Provided, however, that the number of delegates from any particular State, Territory, county, city, or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the code of ethics of this Association.

"The medical staffs of the army and navy shall be entitled to four delegates each."

All other amendments were laid upon the table.

The report of the Committee on the Memorial to Congress in regard to the army and navy staff rank

was then read by the chairman, Dr. Keller, and the following resolutions, after discussion, adopted:

"*Resolved*, That a committee of one from each State and Territory be appointed, with power to fill vacancies, for the purpose of memorializing Congress on this subject, and of securing the co-operation of the several State and County medical societies for the same purpose.

"*Resolved*, That Dr. J. M. Toner, of the District of Columbia, be chairman of said committee, and that the other members of the committee be appointed by the President."

Dr. N. S. Davis then delivered the annual address upon Practical Medicine. This, although containing food for thought, is long, and has not enough of novelty to warrant its reproduction. We extract, however, one paragraph, with the hope that the contributors to the *Philadelphia Medical Times* will never lose sight of the facts it embodies:

"My object is simply to attract your attention to what has appeared to me the strongest barrier in the way of genuine progress both in the science and art of medicine, namely, incomplete observation of facts, deductions from inadequate premises, and the constant use of mere theoretical assumptions or suppositions as though they were demonstrated facts. It is the indulgence of these practices that actually keeps one-half of the professional observers busy in correcting the errors and disproving the assumptions of the other half, and fills our literature with endless contradictions."

Dr. Gross's address on Surgery was confined chiefly to a consideration of the subject of prostitution, and has not been yet reported.

Section One, Practice of Medicine, Materia Medica, and Physiology.—About a dozen members present. A report from the Committee on the Cultivation of the Cinchona Tree was read, and the committee continued, in accordance with their own request.

A very long and elaborate article on The Mechanism of the Encephalic Circulation, by Dr. Reuben A. Vance, of New York, was read.

Section Two, Obstetrics.—A paper upon the Inverted Uterus, by Dr. Bontecue, of Troy, New York, was read and referred to the Publication Committee.

Section Three, Surgery.—The discussion of Dr. Sayre's paper on Fractures was resumed.

Dr. Gregory declined speaking until later. The discussion was opened by Dr. A. Garcelon, Secretary of the Section, who spoke of the great practical value of the question to the profession, and said that while he thoroughly agreed with Dr. Sayre in striving to secure a perfect limb in cases of fracture, and also in aiming at a perfectly accurate adjustment, his own experience showed him the difficulty of succeeding in the latter attempt, and he believed that *no distinct and definite rule* of treatment could be laid down which would show such a series of results as were given in the statistics submitted by Dr. Sayre, for they show a most wonderful absence of shortening. The speaker wished to know how one could learn to measure a limb with absolute accuracy. He said he had been present at many malpractice trials, and had found the opinions of the best surgeons differing materially. When he was a student he was taught to measure through the median line, commencing at the sternum and thence downward over the navel. If one applies the measure to the trochanter, how can one be certain of a satisfactory result? In oblique fractures, how are surgeons to extend and arrange the broken fragments so as with certainty to replace them precisely in their original positions? and if they succeed in that, how shall they keep them there?

In the femur and other long bones, how can the results indicated in the report be obtained? If the position taken by Dr. Sayre is accurate, then the medical profession have much to learn, and the public much to complain of.

Dr. M. Waterhouse, of Wisconsin, asked Dr. Garcelon how he would ascertain with perfect accuracy whether a fracture was oblique or transverse.

Dr. Garcelon said he did not know in cases of doubt; but that when he used the word oblique in this connection he meant that the ends of the bones should slip past and overlap each other. He stated the case of a girl who was of such constitution that he feared to apply the usual dressings to her fractured femur, and whom he had placed upon a flat bed, using the pulley only, and had obtained a successful result.

Dr. Sayre asked how he had kept her from slipping down in the bed.

Dr. Garcelon answered that he had taken no means at all, and had used no counter-extension.

Dr. Sayre said he had seen this done in cases where, by raising the foot of the bed, the body acted as a counter-extension, but he had never seen it on a level bed.

Dr. Chapin, of Grass Lake, said he had known similar cases to be successfully treated on a level bed.

At this stage of the proceedings, Dr. Plummer, of Illinois, read a letter from Dr. Truesdel, of the same State, transmitting a diagram of a fracture-bed, which is merely a triple inclined plane, in which both limbs are equally inclined, and extension is produced by the use of cog-wheels and a ratchet. He stated that for four years he had used these beds with the most gratifying results; that the members of the profession in his section of the country used them and liked them, and that they were not patented articles.

The original question was resumed by the chairman, who said he used in preparing his bandages a solution of silicate of potash and silicate of soda, to which he gave a preference over plaster of Paris, and a decided preference over starch, to which he was strongly opposed. He said it dried very rapidly. On the main question as to whether there was necessarily shortening in oblique fractures of the femur, he was in favor of the view that a certain amount of shortening was necessary.

Dr. Reed, of Ohio, thought that in every case there must be shortening, and he took the ground that in cases of apparent absence of this defect nothing could be known to a certainty. He never yet had seen a skeleton in which the corresponding bones had been perfectly equal in length, nor one in which the difference had been less than one-sixteenth of an inch. Even the text-books are not correct on this point, and in Horner's Anatomy the statement in the text says the corresponding bones on opposite sides of the body are equal, while a foot-note contradicts it.

Dr. Whiting, of Wisconsin, had been surprised at the position taken by Dr. Sayre; and the idea that the theory of the necessary shortening of the long bones in cases of oblique fracture was exploded, alarmed him. With the records of the profession for the past fifty years before them, practitioners had no right to expect such results as those reported from Bellevue Hospital; and if he was compelled to accept the theory, he would, in self-defense, be compelled to retire from the profession.

Dr. Quimby, of Jersey City, did not believe that any surgeon thought himself able to restore ten fractured femurs in a hundred to their original length; that an absolutely accurate measurement was practically impossible, and it is scarcely ever that one finds an exact restoration. The proposition of a perfect cure seemed to him too absurd to require remark. He had seldom seen a case of less than one-half inch shortening.

The speaker adverted to the danger of suits for malpractice, and cited a case in which he knew that a brother-practitioner had narrowly escaped a suit when the difference between the length of the limbs was only one and one-half inches. He said the limb might have been the shorter of the two before the accident, and cited the instance of his own child, in whom, without any perceptible limp, there was a natural difference of one-half inch in the length of the limbs.

Dr. Hughes, of Iowa, thought there were but few present who would agree with Dr. Sayre. He did not question the veracity of the statistics, but if they were true he considered them simply wonderful. He would be glad to hear what Dr. Sayre could advance in support of his position.

Dr. Waterhouse, of Wisconsin, said that if these statements are true, and these figures accurate, we should face the situation, and let the danger of suits come.

There is a reason for this unheard-of success at Bellevue in the appliances at hand, and the constant attendance and care available which country practitioners can never enjoy; and suits for malpractice are generally brought in the country. Backwoods doctors scarcely ever have proper appliances, and cannot possibly give cases constant personal care. The speaker said that he had himself treated many cases in which, with better appliances, he could have produced better results than he had succeeded in doing. He spoke of the question of patients sliding down in bed, and stated that that was a thing which regulated itself, and that in a short time the hips of a patient would produce a depression in the bed which would prevent slipping.

Dr. Pierce, of Illinois, thought the facts should be known, and if surgery has made such advances it should be declared.

Literature in this profession is authority in courts of law, and the later the volume the more weighty its authority. This convention is making literature which will be evidence in the courts of justice, and it is important that that fact should be known. He was startled when he heard that the day of shortening had passed, for he had always had it in his practice. He was prepared to admit the absolute accuracy of the statistics from Bellevue Hospital, presented by Dr. Sayre, but he thought *the measurements were taken too soon*. They were taken when the patient was pronounced cured, while suits for malpractice are scarcely ever brought until after the lapse of months, and in his opinion *shortening goes on after discharge* and when the limb is in use. In one case of his own he was called in to treat the young son of an intelligent mechanic for an oblique fracture of the femur. He explained the whole matter with reference to the possible deformity to the father, who united with him in his efforts to prevent it. Frequent measurements were taken, and when the child was pronounced well there was not the least shortening to be discovered. Some time afterwards the boy was accidentally shot and killed. He was called in to make a post-mortem examination, and found that the bone was one and one-half inches shorter than it should have been, and that the ends had slipped and perceptibly overlapped. He took the bone, and now has it in his possession. He did not believe any patient could be induced to wear apparatus long enough absolutely to prevent contraction, and he thought the loss of only half an inch should be considered a good result.

In continuing his remarks, Dr. Pierce described and advocated the use of the "book" or "Bavarian splint," which is particularly adapted to fractures of the tibia, or of both the tibia and fibula, in which cases it is convenient and easily applied.

This splint can be made by any one who has two

pieces of flannel, a needle and thread, and some plaster of Paris, or the silicates already mentioned by Dr. Gross. The method of construction and application may be illustrated as follows. Place two pieces of flannel (long enough to reach the desired distance, and wide enough to envelop each other) upon each other, and stitch them together longitudinally through the centre, and they will then form four leaves. With two of these envelop the limb, and fasten them together on top, the seam being underneath: this is to keep the plaster case from touching the skin. Upon the other two leaves spread the plaster, and bring them together on top, moulding them to the limb, and when the plaster becomes hard there is a plaster box the exact shape and size of the limb, which can be opened at will, the seam at the back serving as a hinge. With this splint the limb can be looked at every day, and in case of swelling or shrinkage of parts a new one can be adapted to the changed condition. The use of this splint has been recommended in fractures of the femur, but Dr. Pierce had been afraid to try it, although for injuries below the knee he thought it unrivalled. It was recommended for use in compound fractures, a hole being left to allow the escape of discharges, but in such cases he, in his practice, used the fracture-box.

Dr. Sayre, of New York, said he was glad to have been the means of stirring up a discussion on this subject, but he saw he had been *grossly* misunderstood.

A voice.—"No reference to the chair, is there, doctor?" [Laughter.]

Dr. Sayre.—"The chair never misunderstands." [Applause.]

After this little episode the doctor said that he *knew* the statistics presented by himself to be correct; that Dr. Hamilton had made the measurements, and that he was a man who was so violently opposed to the theory that in his published writings he had denied the possibility of any oblique fracture being cured without shortening. For this reason he (Dr. Sayre) had asked him to measure the patients. He said that if seven successive cases should be presented he would agree to give up his opposition to the theory. He found the cases, and surrendered.

Dr. Sayre now turned and said, "Did Dr. Gregory say yesterday that it was impossible?"

Dr. Gregory answered, "Yes."

Dr. Sayre then said he was glad to have found an authority at last; that the reasons he had concluded to make a report were, as he stated on Tuesday, because he had heard of practitioners who clung to obsolete theories, and now he was glad to find that there had been a necessity for his doing so. He then read an article from the *Medical Journal*, signed by Dr. Hamilton, sustaining his position. He said the credit of the results at Bellevue is not due to the attending surgeons, but to the young men of the institution, who make the preliminary arrangements and have the care of the patients.

In reference to the Bavarian splint, he was opposed to opening or removing it to look at the limb. When a fracture is well adjusted, leave it alone.

The statements that accuracy of measurement was impossible, which had been made by some of the speakers, had astounded the doctor more than a little, and he called their attention to the accuracy of measurement by which the stones in the very building in which they sat had been measured and cut by one set of men and perfectly matched by another set.

Dr. Sayre then took up the mode of treatment he had advocated on Tuesday, produced his machine of wood and rubber, and briefly repeated his theory in regard to extension and counter-extension. He claimed that there is never irritation of the muscle when there is only normal traction. If there is only enough exten-

sion to produce a normal condition, then there is retention,—*fixation*. Too much extension is abnormal, produces irritation, and is often the cause of non-union.

Extension and counter-extension should be applied the instant of seeing the patient, and then—*fixation*. There are no circumstances when something cannot be found to effect this. Machinery is the curse of the profession, and there is scarcely a country doctor who has not in his office a lot of worthless and expensive machines called "surgical appliances."

In setting a limb, the assistant who holds it in position while the surgeon is applying the bandages is in the most responsible position. If there is a single continuous piece of skin (no matter how crooked or narrow) for a guide, then the limb can be put in position, be held by an assistant, and properly attended to.

The speaker said that in thigh-fractures he used the triple inclined plane. He disclaimed any desire to "lay down the law," and concluded by claiming that a discussion of this kind would not have the authority of a carefully-written book.

Dr. Pierce stated that in opening the Bavarian splint to look at the limb he removed only one leaf at a time, and that he had the limb held in position by an assistant; that he considered it important to look at the limb, verify adjustment, and see its general condition. He adhered to his statement as to the impossibility of making accurate measurements, and stated that he did not believe there were any seven men in the room who would agree on a measurement of the distance between the two entrance-doors.

Dr. Garcelon asked Dr. Sayre how he would treat a fracture of the thigh in a boy five years old; how he would find out if the length was right, and how he would secure health during treatment.

He said he also wished an opinion in another case. A young man, of 16 or 18 years, fell on the sidewalk and broke his arm; a competent surgeon set it, and said it was perfectly adjusted; a starch bandage was applied, and no pain was felt after the first day. On the tenth day the speaker was called in, found gangrene had set in, the soft parts sloughed away from the wrist to the elbow, the bones slipped, and amputation became necessary.

Now, what was the cause?

Dr. Sayre answered that with children treatment was difficult, but showed with slips of paper his method of disposing the little patient upon an apparatus formed with two boards so that the leg actually sets itself. Treatment with plaster is difficult, because children are so fat that shrinkage of the limb is certain, and it will rattle about in its plaster case like a pea in a box.

Dr. Garcelon.—"How do you keep the child from twisting about?"

Dr. Sayre.—"He finds out what hurts him, and it is an astonishing fact that children like to be comfortable."

Dr. Garcelon.—"What do you do in the case of an ununited fracture?"

Dr. Sayre.—"Rub the ends of the bones together, twist them around, and break things generally."

Dr. Sayre here, with the assistance of a gentleman whom he used as a subject, illustrated his mode of setting, extending, and "fixing" a fractured thigh, with the aid of a simple apparatus contrived by Dr. Figaro, a young physician at Bellevue.

Dr. Gregory, of Missouri, said, "I think I answered Dr. Sayre when I said yes. I say I think there is no such thing as a firm cicatrix without contraction." The doctor affirmed that there would be no such thing as healing without new matter; that there must be softening, and there must be loss of material from the incident inflammatory action.

He said he was astonished at hearing Dr. Sayre's remark about fearing displacement in case of removing

the Bavarian splint, and asked if he thought he could put plaster on any limb so tight as to prevent muscular action and contraction. There is no such thing as quiescence in the muscles; there is always tonic action tending to contraction. As long as the muscles live they will act, and will force the fractured bones to slip slowly past each other. He insisted that extension and counter-extension would not prevent this, in addition to the cicatricial contractions. He concluded by saying, "I again assert that the man who believes he has done it is simply mistaken. I think Dr. Sayre himself believes what he has said."

Dr. Lockford, of Missouri, wished to correct Dr. Sayre in a matter of fact. The system of treating fractures by flexion was inaugurated about the middle of the last century, and was once very popular. He then discussed the theoretical and practical difficulties of the question, and concluded by saying that he believed with Dr. Sayre that perfect cures can be effected, and that the profession should strive for perfection.

Dr. King, of Philadelphia, at the request of Dr. Sayre took the floor, and stated that he fractured his thigh over a year ago, and that now there was no apparent and only a very slight actual shortening of the limb.

The discussion was continued some time longer, after which Dr. King moved that Dr. Sayre's paper be referred to the Committee on Publication.

Dr. Quimby, of Jersey City, moved to substitute for Dr. King's motion the following preamble and resolution:

"Whereas, There seems to be some uncertainty in the minds of the profession in reference to their treatment of fractures of the long bones, therefore,

"Resolved, That it is the opinion of this section that it is nearly impossible to treat fractures without shortening."

The substitute was lost, and the paper referred to the Committee on Publication.

The Section of *Public Hygiene* had various papers before them, mostly not of sufficient interest to render necessary their reproduction here.

THIRD DAY.

The Association met punctually at 9.30 A.M.

After some business not of general interest, the report of the Committee upon the President's Address was received. *Inter alia* it urged the perfecting of the State and County organizations everywhere, an extension of the time of sitting of the Association from three days to four, and offered the following resolutions:

"Resolved, That in view of the lack of time in which to properly transact the business of the Association, an extension of one day is deemed advisable:

"Resolved, That the President appoint a committee of five, of which he shall be chairman, to elaborate a plan for the organization of an International Medical Congress, and report at the next meeting."

Suitable resolutions in regard to the death of the late Dr. Henry Miller were read and adopted.

Drs. S. D. Gross, of Philadelphia, J. M. Keller, of Louisville, and E. S. Gaillard, of Kentucky, were appointed a committee to prepare a memorial.

An appeal from the Boyle County Medical Society, of Kentucky, was read by Dr. Keller, and the following preamble and resolutions, after discussion, were adopted:

"Whereas, A most laudable effort has recently originated in the Boyle County Medical Society, of the State of Kentucky, and in the Kentucky State Medical Society, to create a fund for the erecting of a statue or some other suitable memorial in honor of Dr. Ephraim McDowell, 'the father of ovariotomy,' English writers to the contrary notwithstanding, who lived in the town of Danville, in the State of Kentucky, and who per-

formed in that town the first ovariectomy, in the year 1809;

"Resolved, That the American Medical Association most earnestly endorse the action of said County and State Societies, and as urgently commend the object to the generous consideration of the medical profession of the world."

After various discussions in regard to matters of more or less interest, Dr. A. Nelson Bell, of Brooklyn, New York, read an excellent address upon *The Waste of Life*, having an especial reference to New York and Brooklyn. In regard to that most diabolical of all the fruits of modern society, the New York tenement-house, Dr. Bell said,—

"The raid of the sanitary police in New York last year, in view of the expected cholera, discovered thousands of people actually living in holes in the ground, a dozen or more in a huddle, in holes nine or ten feet square, swarming with vermin, and rotten with disease—no less than twenty thousand of these *trogloodytes* living like moles and bats in the dark, poisoning the atmosphere around and sucking the life-blood of the people. In the tenement-houses of New York there are many single rooms occupied by from ten to fifteen persons of both sexes, and frequently by several families. There are structures from four to six stories high, divided into hundreds of rooms, crowded with men, women, and children, smothering for the want of fresh air, and in dirt and foul odors horrible to contemplate. And there are, not uncommonly, near to such buildings as these, adding to the stifling condition, yards which, with the gutters, are the common filth receptacles for the out-throwings and are the wallowing-places of the children; the streets, as filthy as the gutters, for the young girls, and rum-holes at every corner for the parents. And these tenement-houses are the homes of more than half of the children of New York. In them is carried on the perennial 'slaughter of the innocents' of more than two years old and under, in comparison with which the crime of Herod sinks into insignificance.

"Such surroundings obtund and destroy human sensibilities. The occupants of such dwelling-places become an easy prey to the sensual excitements of alcohol and other debasing agencies and influences. As people become accustomed to dirt, they cease to recognize its presence and to exert themselves to avoid it; there is no limit to the downward tendency. The same broad road to disease and death is the highway to moral degradation; and that such an institution should breed disease and death, that it should be the hecatomb of children, that it should sustain liquor-stalls by the thousand, and supply the ghastly gayety which flaunts beneath the gaslight and makes night hideous, that it should send the boys who escape the slaughter to State Prison—that the tenement-house should do all these things, and more than words can utter, is perfectly consistent with its appointments. And yet, to repeat, more than half of the children of New York are born in tenement-houses; but New York is called a Christian city."

We make the following extract also from this address:

"The total number of deaths in Brooklyn last year was 10,968, and not less than one-fourth of them were accelerated by defective drainage. And yet Brooklyn is no exception in this regard. On the contrary, the death-rate of Brooklyn compares favorably with other of our large cities, which is abundantly shown by the following examples: The total annual death-rate of Brooklyn from consumption last year was 3.47 per 1000 of population (census of 1870), and on the whole number of deaths the percentage for consumption was 12.55. In the city of New York, on an estimated population at the present of 1,000,000, there are of deaths from consumption 4.13 per 1000, and 14.22 per cent. of the total mortality. Boston, 3.96 per 1000 of population,

13.84 per cent. of total mortality; Philadelphia, 3.05 per 1000 of population, 13.65 per cent. of total mortality; San Francisco, 2.74 per 1000 of population, 14.12 per cent. of total mortality; Albany, 3.43 per 1000 of population, 15.50 per cent. of total mortality; New Orleans (where the benefits of a mild climate opposed to consumption are condoned by defective drainage), 3.96 per 1000 of population, 13.84 per cent. of total mortality. By States: of the total mortality in the United States, 12.45 per cent. was caused by consumption; in New York, 16.17 per cent.; District of Columbia, 21.19 per cent. A concise table of the ratio of the deaths from consumption in every State in the Union may be found in the 'Dictionary of Elevations and Climatic Register,' by Dr. J. M. Toner. Under approximate temperature, the ratio of mortality from consumption in regard to defective drainage will be found scarcely less deviating than miasmatic fevers."

After a vote of thanks had been tendered to Dr. Bell for his address, the Committee on Prize Essays reported that none, in their estimation, worthy of the prize had been offered. The report was accepted.

A communication from the Philadelphia County Medical Society was then read, inviting the American Medical Association to hold its annual meeting during the Centennial year (1876) at Philadelphia. The subject was referred to the next meeting of the Association.

The following gentlemen were then announced as having been appointed delegates to foreign bodies: R. J. Lewis, D. G. Brinton, T. M. Drysdale, Philadelphia; E. C. Howard, E. Seguin, New York; L. C. Law, California; J. D. Jackson, Kentucky; A. J. Erwin, Mansfield, Ohio; George W. Burton, Mitchell, Indiana.

A report from Dr. Seguin concerning his visit abroad as representative of the American Medical Association was next read. It related especially to an effort for harmonizing our means of observation and of record, and stated that the British Medical Association had ordered the printing of Dr. Seguin's address upon the subject before them, and that the French Association for the Advancement of Science had voted the nomination of a commission to arrange the preliminaries of an international agreement upon the subject. It concludes as follows:

"These considerations could be much enlarged. To save time, I cut them short, and conclude by asking the American Medical Association to form an international commission of physicians of high standing, speaking the European languages, and designing to go to Europe this summer.

"To charge them to represent the American Medical Association before the British Medical Association, the German and French Associations for the Advancement of Science, and other kindred societies; to promote interchange of ideas, and particularly to co-operate with them in any plan, scheme, or organization which would have for direct object the uniform establishment and propagation of the methods and instruments of positive observation. And, finally, to invite them to report on the progress of this work at the next meeting of this Association."

A proposal to amend plan of organization was submitted by Dr. Adams Jewett, of Ohio:

"First sentence of paragraph eight of Article II., p. 403 of Transactions for 1873, reads as follows:

"The *permanent members* shall consist of all those who have served in the capacity of delegates, and of such other members as may receive the appointment by unanimous vote, and shall continue such so long as they remain in good standing in the body from which they were sent as delegates, and comply with the requirements of the by-laws of this Association."

"I propose that this sentence be amended so as to read as follows:

"The permanent members shall consist of all those who have served in the capacity of delegates, and of such other members as shall have received the appointment by unanimous vote, and of all others who being members in good standing of any State or local medical society entitled to representation in this body shall, after being vouched for by at least three members, be elected to membership by a vote of three-fourths of the delegates in attendance, and shall continue such so long as they remain in good standing in the body of which they were members when elected to membership in this Association, and comply with the requirements of its by-laws."

This was laid over for one year.

The report of the Librarian was read and accepted, and resolutions were passed empowering the Committee of Publication to arrange exchanges with journals, naval and military bureaus, etc. The success of the library movement is most encouraging, as the number of titles upon the shelves already reaches four hundred and thirty-one, an exhibit rendered still more flattering by the fact that many of these are odd or incomplete volumes.

At the request of Dr. Woodward, U.S.A., the Committee on the Nomenclature of Diseases was continued.

In accordance with a resolution offered by Dr. William B. Atkinson, it was agreed that a suitable medal be prepared, having on one side the likeness of Dr. N. S. Davis, and on the other the name and date of the organization of the Association, and that hereafter one such medal be presented to each delegate upon his becoming a member.

The judicial council made a report exonerating Dr. W. T. Myers of all charges made against him.

Section One.—Dr. L. D. Bulkley read an article on "A New Antipruritic Remedy," which was referred to the Committee on Publication. The principal facts in Dr. Bulkley's paper are as follows:

Eighteen months ago he presented to the profession the *liquor picis alkalinus*, which had proved itself valuable in certain cutaneous affections in relieving itching in many instances, and whose value in this and other directions is daily becoming more evident. The failure of this as an antipruritic in some cases, as might be expected, led him to the adoption of the compound presented, which had thus far rendered inestimable service, but which had not to his knowledge been heretofore known. A remedy formed of hydrate of chloral and gum camphor, equal parts, rubbed well together, was found to be convertible into a transparent, colorless fluid, of the consistency of glycerin. It at once occurred to Dr. B. that it would be of value in cases presenting the above symptoms, and he had long employed the chloral internally with good results. He had some ointment prepared of pulverized gum camphor, hydrate of chloral, and rose ointment, which produced excellent effects when rubbed on the healthy skin. The compound was also soluble in almond oil, alcohol, and ether. Two cases were cited in which the remedy had been employed with satisfactory results.

Without any extended discussion, the paper was referred to the Committee on Publication.

After this there was a sort of running debate upon the President's address, and it was finally agreed that, in accordance with its suggestions, two committees should be appointed by the chair,—one on Meteorological Observations, Dr. Toner, of Washington, to be chairman, and the other on the Observation of Disease, Dr. N. S. Davis to be chairman.

Dr. Garrish, of New York, then read a long paper upon hydrophobia, containing an interesting history

of the disorder, but nothing at all novel, unless it be the suggestion that bronchotomy should be resorted to in the treatment of the disorder.

Dr. E. Seguin, a New York delegate, made an exposition of his method of mathematical thermometry, and an exhibition of his thermometers. The instruments differ from the old ones in two points: first, zero is at the point of human health (old 38 deg. 40 min., F.), instead of at the point of melting snow of the weather thermometer; second, a special instrument is devised to measure the heat of limited surfaces, like the forehead of a student, the seat of formation of a tumor, etc.

These instruments serve to create the new method of observation advocated by Dr. E. Seguin. Instead of tracing the march of disease by curves difficult to make, and still more difficult to read correctly, he uses only figures, and sums up all the phenomena—heat, pulse, and inspiration—by figures which, tabulated by days and weeks, permit a mother to be more positive in her appreciation of the condition of her sick child than many physicians can realize by simple guessing.

The thanks of the Section were voted, and the paper was ordered to be printed.

Section Three.—Dr. Beard made an extended address upon the use of electricity, in which he arrived at the following conclusions:

1. That certain benign tumors, as goitres, cystic tumors, and naevi, can be made to diminish or to disappear under electrolysis.

2. That fatty tumors and many enlarged glands usually do not much diminish under electrolysis, and sometimes will not diminish at all.

3. That malignant tumors will not usually diminish, and rarely, if ever, disappear, under electrolysis; but the pain connected with them can be treated most successfully, not only by electrolysis, but also by simple external electrization.

4. That malignant tumors, when sufficiently accessible and not too far advanced, may be treated by the method of *electrizing the base, or working up the base*, as Dr. B. terms it, and this method promises more permanent results than have been obtained by the usual treatment.

5. That certain diseases of the skin—herpes, eczema, and prurigo—may be treated by different methods of using electricity with the highest success.

6. That diseases of the skin may be treated by local and *central* methods of using electricity; but some of the most brilliant results in the treatment of chronic eczema have been obtained by galvanizing the nerve-centres, in the method of *central galvanization*, without making any application whatever to the diseased parts. The results of this method of treatment seem to show pretty conclusively that chronic eczema is to a considerable extent dependent on the central nervous system.

The question of fractures was again brought up.

Dr. J. W. Hughes, of Pennsylvania, stated that the action of the Section in reference to the rejection of Dr. Quimby's motion in reference to Dr. Sayre's paper upon fractures looked better for Dr. Sayre than it did for the gentlemen present, a large majority of whom were undoubtedly opposed to the theories advanced and sustained by the statistics furnished. He therefore, for the purpose of placing the Section right before the profession, offered the following:

"Whereas, The members of the Surgical Section of the American Medical Association have listened with interest to the report of Prof. Sayre, of New York, on the subject of fractures, and whereas, statistics accompanying said report evince in the institution represented unusual results; therefore,

"Resolved, That the Section, after free discussion of the report, and its reference to the Publishing Com-

mittee, would express their opinion, based upon experience, that the results, in relation to shortening following fractures, are better than can be looked for in general practice."

A somewhat excited discussion of scarcely more than mere personal interest followed, and was brought to a conclusion by the adoption of the resolution.

Dr. William P. Pierce, of Lamont, Illinois, offered the following, which was adopted:

"*Resolved*, That this Section hereby requests of Prof. Sayre that as far as possible he should cause a second measurement to be made of all these cases, and report the result of such measurement at the next session of this Association."

In the afternoon session Dr. D. O. Farrand, of Detroit, introduced two cases of oblique fracture of the femur in boys, which he claimed to have cured, one with only a very slight shortening, the other with absolutely none, and asked those interested to examine the boys. The larger of the two was ten years old; his fracture had taken place six years previously, and he it was whose cure was said to be perfect. He was taken into the jury-room, undressed, and, on motion of Dr. Sayre, was measured by a committee of all who did not believe in the completeness of the cure. Nearly every one present examined him, and a number of measurements were taken, some finding the leg which had been broken to be the shorter, while others claimed the contrary. Among those who stated that absence of shortening was totally impossible was Dr. J. T. Hodgins, of St. Louis, who was apparently much chagrined when he reported that the left leg was the *shorter*, when it turned out that the right was the one which had been broken. He, however, claimed a triumph, as he said the result only showed the accuracy of his position "that a correct measurement was an impossibility."

Dr. Sayre was evidently delighted at this evidence in favor of his theory of the possibility of perfect cures, and not only that, but that it also went to sustain him in his statement that the younger members of the profession were the most successful men.

Section Four.—Papers were read by Dr. E. Lloyd Howard, of Baltimore, on Emotional Insanity, and by Dr. A. N. Falley, on the Relations of Psychology to Medicine, and were referred to the Publication Committee.

Section Five.—Various matters were discussed, the most important being as follows:

A resolution offered by Dr. H. B. Baker, of Lansing, Michigan, was adopted. Under it Drs. Baker, H. A. Johnson, of Chicago, and Toner, of Washington, were appointed a committee to draft a bill for the establishment of a National Council of Health at Washington, and otherwise to forward the proposed measure.

Dr. Horner offered his annual resolutions in regard to alcohol, and, after a long discussion, had the satisfaction of having them passed, sixteen members being present.

FOURTH DAY.

The Association was called to order at the usual hour.

On motion, Dr. E. W. Jenks was added to the delegates authorized to represent the Association before similar foreign organizations.

On motion, the following were appointed a committee to digest a plan for an International Medical Association: Drs. J. M. Toner, of the District of Columbia; N. S. Davis, of Chicago; Alfred Stillé, of Pennsylvania; Austin Flint, Sr., of New York, and J. S. Billings, United States Army.

THE NOMINATIONS.

Dr. H. T. Byford, of Colorado, submitted the report of the Committee on Nominations, which, after various corrections, was adopted, as follows:

The Committee on Nominations respectfully report that they suggest the following gentlemen for the various officers named:

President, Dr. W. K. Bowling, Tennessee.

Vice-Presidents:

1. Dr. William Brodie, of Michigan.
2. Dr. J. J. Woodward, of United States Army.
3. Dr. H. W. Brown, of Texas.
4. Dr. H. D. Didama, of New York.

Treasurer, Dr. Caspar Wister, of Pennsylvania.

Librarian, Dr. William Lee, of District of Columbia.

Committee on Library, Dr. Johnson Elliott, of District of Columbia.

Assistant Secretary, Dr. Will. Walling, of Kentucky.

Committee of Arrangements: Drs. Edward Richardson, Chairman; Lawrence Smith, Robert Gale, James Holland, Henry Bullitt, J. M. Keller, D. W. Yandell, Lewis Rogers, R. C. Hewett, all of Louisville.

Committee on Prize Essays, Drs. J. A. Oetlerloney, L. P. Yandell, J. D. Jackson, all of Kentucky; Theophilus Parvin, T. M. Stevens, both of Indiana.

Committee of Publication, Drs. F. G. Smith, Wm. B. Atkinson, D. Murray Cheston, Caspar Wister, Alfred Stillé, all of Pennsylvania; William Lee, of District of Columbia; H. F. Askew, of Delaware.

Next place of meeting, Louisville, Kentucky.

Time of meeting, first Tuesday in May, 1875.

The committee also report the following nominations for

Chairmen and Secretaries of Sections for 1875:

1. Practice of Medicine, Materia Medica, and Physiology, Dr. Austin Flint, of New York, Chairman, and Dr. J. K. Bartlett, of Wisconsin, Secretary.

2. Obstetrics and Diseases of Women and Children, Dr. W. H. Byford, of Illinois, Chairman, and Dr. S. C. Bussey, of District of Columbia, Secretary.

3. Surgery and Anatomy, Dr. E. M. Moore, of Rochester, New York, Chairman, and Dr. Thomas S. Latimer, of Maryland, Secretary.

4. Medical Jurisprudence, Chemistry, and Psychology, Dr. Jerome Cochran, of Alabama, Chairman, and Dr. G. A. Moses, of Missouri, Secretary.

5. State Medicine and Public Hygiene, Dr. H. I. Bowditch, of Massachusetts, Chairman, and Dr. H. B. Baker, of Michigan, Secretary.

Judicial Council, Drs. J. K. Bartlett, Wisconsin; R. H. Gale, Kentucky; J. B. Johnson, Missouri; J. R. Bronson, Massachusetts; B. H. Catlin, Connecticut; Franklin Staples, Minnesota; W. T. Briggs, Tennessee, in place of the seven whose terms expire at this meeting. Dr. A. N. Talley, of South Carolina, for two years, to fill vacancy. The rest of the present council continued.

The reports of the Publication Committee and of the Treasurer were read, and, excepting those portions which referred to the resignations of the Chairman of the Committee and of the Treasurer, were accepted. By special motion, the Association declined to accept the resignations alluded to.

The death of Dr. George Mendenhall, ex-President of the Association, was announced, and a committee was appointed to draft suitable resolutions.

After elaborate resolutions of thanks to the medical profession and others of the citizens of Detroit for their careful hospitality had been acted upon, Dr. Keller, of Kentucky, offered the following resolution, which was adopted:

"*Resolved*, That, in furtherance of the views expressed by Dr. Gross in his valuable address touching

a proper legislation to prevent the spread of syphilis, a committee composed of Dr. Gross, Dr. N. S. Davis, Dr. J. M. Toner, Dr. Marion Sims, and Dr. John Morris, be appointed to report at the next meeting the most feasible plan for securing such legislation."

In the remaining hours of the session various business, not of general interest, was transacted.

A paper by Dr. Paul F. Eve, on Surgery in the West, was read, and the following amendment to the Constitution was offered by Dr. H. B. Baker, of Michigan, which, under the rules, was laid over until the next session of the Association:

"The officers of the several Sections shall be nominated by the Sections in and for which said officers are to serve."

It was decided that the next meeting should be held at Louisville, Kentucky.

TRANSLATIONS.

PARENCHYMATOUS INJECTION OF CARBOLIC ACID AS AN ANTIPHLOGISTIC (C. Hüter, of Greifswald: *Centralblatt*).—Although the antiphlogistic use of carbolic acid externally as a surgical dressing is sufficiently well known, and likewise its use hypodermically in treating intermittent, Hüter claims to be the first to bring into notice the favorable results attained in his clinic by its use as an antiphlogistic, by means of parenchymatous injections. The solution which was used in this treatment was of the strength of 2 per cent. by weight; and the injections were made with an ordinary hypodermic syringe, which held about 0.9 grammes of the solution, or rather less than 0.02 grammes of carbolic acid. More than two injections of this amount were never administered in immediate succession, and they were never followed by any symptom of carbolic acid intoxication, nor even by any darkening of the urine. If more than two injections were made, an interval of a day or two was allowed to intervene, lest evil consequences should result from any cumulative effects of the drug. The operation was in no case followed by pain or swelling; indeed, the absence of pain was so complete that even small and sensitive children gave no evidences of suffering. The antiphlogistic effect of the injections was well marked in almost every case, and the following are adduced in illustration:

1. Synovitis hyperplast granulosa (tumor albus) of the knee-joint. The injections were made into the central part of the joint, the needle even touching the surface of the articulating cartilages. Diminution of pain followed, and also a noticeable falling in the evening temperature, which had previously been persistently high; and a reduction of the swelling was also noticed. As the disease was of a chronic character, frequent repetition of the injections at intervals of two or three days was needed.

2. Subacute glandular swellings with a tendency to supuration; buboes of the inguinal and femoral regions.

Here there was a diminution of the pain and also of the redness of the skin and the œdema; the gland became rounder, and gradually diminished in size. Numerous injections, however, were needed before entire recovery.

3. Acute phlegmonous inflammation of the subcutaneous and subfascial connective tissue. The most central spot of the inflammation should be chosen for the introduction of the nozzle of the syringe, and if the phlegmon is of large size two injections at different situations should be made.

The operation in this case was followed by diminution of the fever and pain, and in a few hours by contraction of the tissues involved. Recovery without supuration

occurred when this process had not already begun at the time the injection was made.

4. Traumatic erysipelas. In this disease, injections were made at the edges of the inflamed area, with the view of preventing the spread of the process upon the sound skin.

The desired object was attained, but in no case was the attempt made to cut short an attack by making injections around the entire circumference of the diseased area.

Hüter lays great weight upon the parenchymatous nature of the injections, and insists that to obtain its full antiphlogistic effect the carbolic acid must be introduced into the articular cavities of the larger joints, into the perivascular connective tissues, and into the interior of the lymphatic glands; and that when so administered it will produce the most satisfactory results.

He hopes, too, that this mode of treatment may prove to be of value not only in surgical practice, but likewise in disease of the internal organs of the body. He thinks that there are no weighty objections against injections of this nature into the lungs, spleen, liver, and kidneys; but before proceeding to these, careful experiments upon the inferior animals must be made. Care must always be taken to avoid the introduction of the carbolic acid into a vein, so that its poisonous effects shall not be caused.

In the treatment of benign tumors he has not as yet succeeded in attaining complete recovery, and he thinks it probable that carbolic acid would be advantageous also in the treatment of malignant growths, since it possesses anæsthetic qualities and is not irritating in its effects.

W. A.

ANGEIOLEUCITIS OF THE LUNG.—A memoir on this affection was read before the *Soc. Méd. des Hôpitaux* recently by Dr. M. Renaud. Dr. R. in this memoir gives an account of several cases of the disease occurring under his observation and that of others, and concludes as follows:

1. There exists a lesion of the lungs heretofore undescribed in our classical treatises, and which is characterized by varicose turgescence of all the lymphatic vessels, superficial and profound.

2. This lesion merits the name angeioleucitis. While it has a certain relation to cancer, particularly to cancer of the stomach, yet one cannot deny the facts when generalized angeioleucitis of the lungs is said to have been developed without any cancerous affection. Probably angeioleucitis of the lung may be simple or specific in its character, both varieties presenting great similarity from an anatomico-pathological point of view.

3. Angeioleucitis may become a grave complication, and may determine death by the lungs of patients attacked by primitive lesions of other organs.

A. V. H.

COLD IN TYPHUS (*The Practitioner*, April, 1874).—In a paper written in 1801 by Dr. Alvey, and found by Dr. Wilson Fox in an old manuscript volume of the "Report of the Proceedings of a Medical Society in the Country," the author advocates the judicious use of cold baths or tepid spongings in typhus and its varieties. He says he has employed them with a view of diminishing the unnatural heat of the surface, and thus curtailing the duration and lessening the violence of the febrile paroxysm.

NEW ANTISEPTIC OINTMENT.—Lister is said to be using the following, with great success. Paraffin two parts, white wax one part, oil of sweet almonds two parts, boracic acid (powdered) one part.—*Student's Journal*.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JUNE 13, 1874.

EDITORIAL.

THE SCIENCE OF HOMŒOPATHY.

HOMŒOPATHY is a fact; facts are obstinate; facts are stumbling-blocks; facts are stepping-stones over which the human intellect climbs towards infinity. Oppressed often with a sense of impotence; longing for new powers over disease as the patriot longs for new power in his country's life-battle; humble as the man who has been tried and found wanting; honestly have we turned to homœopathy as a fact, to find, if possible, some good existing thing in it,—the truth in the midst of error,—the source of its vitality,—and hitherto we have only learnt this lesson—that disease is usually self-limited; that the power of mind over the body is most wonderful; that hygiene is supreme; that honest men warp their theories unwittingly, and practise as they think in accordance with a theory when they are really acting contrary to it; and, finally, that complete knaves do most abound. We have heard a homœopath defending with the stolidness of ignorance the use of aconite in fever, because (God save the mark!) the aconite causes fever; of opium in diarrhœa, because opium causes diarrhœa; and have marvelled at the perversity of the human intellect.

After all, however, the great fact of homœopathy remains, and, we confess, is in a measure to us a stumbling-block; and our various failures have not deterred us from hoping that we may finally discover some further truth which shall make a stepping-stone out of the stumbling-block. Consequently, when a book by a Western homœopath of prominence, en-

titled "The Science of Homœopathy," was put in our hands, we seized it with avidity, and started to read it carefully; we find it a farrago of practical sense, unmitigated nonsense, honest aspirations after truth, blind credulity, and a still greater blindness as to the true relations of things.

When a man tells us that constitutional syphilis is caused by an undue suppression of a chancre, we have the gauge of his mental calibre; and this measure is a fair one of the author of the book before us.

There is one thing, however, in the book that is of great interest, as marking an era in the history of homœopathy. As is well known, one of the original doctrines of Hahnemann was long since ignominiously thrown overboard by his followers; and now the second of the trio follows on the same route, and it is earnestly claimed that the only really vital portion of Hahnemannism is the doctrine of *similia similibus curantur*, and that the homœopath may on suitable occasions use large doses.

It seems to us scarcely possible that homœopathy can long survive this new departure. Take the case of aconite: as is well known, it always depresses in any dose, the amount of depression being proportionate to the amount ingested. A person depressed might recover after the ingestion of infinitesimal doses of the remedy, but if it were used in full amounts under the banner of *similia similibus curantur*, even the wayfaring man, though a fool, could not fail to perceive the disastrous results.

FOOD OF THE MASTODON.

DR. J. GIBBONS HUNT, of this city, recently received from Charles Stodder, Esq., of Boston, a mass which is said to have been recently extracted from such a position within the skeleton of a mastodon as to show that it had formerly been in the stomach of the animal. After getting rid of all opacity in the material, it was at once seen that fragments of plants formed the bulk of it. Both cryptogams and flowering plants were present. Stems and leaves of mosses of several species were in large abundance, with cells as distinct as though gathered yesterday. Large numbers of minute, round and black, opaque bodies, which doubtless are spores of the mosses, were quite apparent. A filament of a confervoid plant was also discovered; cells in a single linear series, square, and similar in appearance to some now found living in the water. We have seen one stem of a flowering plant an inch long, the central part decayed and gone, the outer layer of cells as distinct and perfect as when alive.

Many fragments of marsh plants,—not mosses,—but too much broken to justify a guess as to species, and shells of entomostracæ and ciliated organisms, perhaps infusoria, could be clearly detected. There was not one sphagnum leaf in the lot.

If the mass was really ever in the stomach of a mastodon, the animal died soon after dinner, because the plants were not much digested.

That the mastodons which once roamed the forests we now call our own were vegetable feeders their dentition plainly shows, and the examination indicates also that they were omnivorous in taste, not being confined to the soft cryptogams of the bogs, but eating the branches of shrubs, and, perhaps, young trees as well; for bark and well-marked spiral vessels were present. No fragment of coniferous plant could be detected, and it is probable that mastodons did not eat that class of plants.

REVIEWS AND BOOK NOTICES.

LECTURES ON THE DISEASES OF INFANCY AND CHILDHOOD. By CHARLES WEST, M.D. Fifth American, from the Sixth English Edition. Philadelphia, H. C. Lea, 1874.

The verdict of more than a quarter of a century renders unnecessary, on our part, any words concerning the merits of the book before us. Our only proper task is to announce the birth of a new edition. The storehouse out of which its materials were taken has been enriched by seven years of clinical observation since the last English edition,—years apparently full of fatness, for we read that they have furnished the records of seven hundred and forty-three cases of sufficient interest to be worthy of noting. The present book rests, then, upon the experience gleaned from two thousand cases and nearly six hundred post-mortem examinations. Dr. West's work has always seemed to us pre-eminently the offspring of a bedside rather than a library physician, and to possess all the peculiar merits and some of the demerits of a book of such character. In the present edition we find nothing to alter this conviction.

H. C. W., JR.

THE TREATMENT OF SYPHILITIC DISEASES BY THE MERCURIAL VAPOR-BATH. Compiled from the Fifth London Edition, by Dr. JOHN W. FOYE. A. Williams & Co., 135 Washington Street, Boston, Massachusetts, 1874.

We once heard an observant physician state that he could tell the syphilographers of a city by their equipage being so much more showy than those of their brethren. The author or editor of the present work evidently carries his taste into literature, for the little brochure is about the handsomest medical book we have met with. Beautifully printed upon extra heavy tinted paper, encased in the finest of Turkey morocco and marbled paper; it looks like the latest volume of poetry, prepared for my lady's boudoir; yet the text is redolent of the charnel-house of vice.

The book belongs to the great natural order of Composite. First, after the Preface, there is an essay by Dr. Foye, upon the method of exhibiting the mercurial vapor-bath; then the brochure of Dr. Langston Parker, late of Birmingham, England, "The Mercurial Vapor-

Bath;" next, "The Calomel Vapor-Bath," by Henry Lee, of London; and finally, Mr. Parker closes the rear file by "Notes and Cases illustrative of the Effects of the Mercurial Vapor-Bath upon various forms of Constitutional Syphilis."

It is said that a new style of architecture threatens to arise from the ignorance, independence, and practical sense of American builders. As all these several essays are separately paged in the present brochure, we have a new type of book-architecture; let us hope, however, that it will never become national. Of course, like most books published in favor of any particular mode of practice, the present composite claims that in mercurial fumigations is the *summum bonum* of infected humanity; or, as Dr. Foye puts it, "So unerring is its success that I claim it to be the most perfect system for the cure of syphilitic disease known to medicine."

After examining the evidence, we are unable to agree with this verdict, but do believe that the bath often does great good, and that every one who treats many cases of the disease ought to be well acquainted with the method of its employment. To those desiring such knowledge, we commend this little brochure.

H. C. W., JR.

THE PSYCHOLOGY OF SCEPTICISM AND PHENOMENALISM. By JAMES ANDREWS. James Maclehore, Glasgow, 1874.

Two data support the theorems of this little book, the first being that "Phenomenon is that which appears to be, but is not, what it appears;" the second, "that scepticism is the legitimate fruit of philosophy."

A book which expresses thinking we always welcome to our table with much relish; albeit we do not find ourselves at all times repaid for the greeting we give. He has read but little of the metaphysicians who discovers not that the fallacies which render their obscurities a by-word and jest come not from their being what metaphysicians should be, but, on the contrary, from their being just what they should not be. "Metaphysics," said Aristotle, "is that which comes after physics;" but the metaphysicians of the present day, in spite of the great master, will insist, most of them, on being a-priorists. Hence it is impossible that they should be aught else than sophists, save as the result of some happy accidental stumble upon truth. Mr. Andrews, while he does not himself at all seem to recognize it, is a Berkeleyan, and not what the metaphysician should be, an a-posteriorist; for while it is true that he discusses color, and space, and form, yet it is with the speculative fancy of a Lucretius, rather than with the demonstrative capability of a modern physicist.

Far from being true is it that philosophy has, as its legitimate fruit, scepticism. Scepticism is grown of a pseudo-philosophy. Wisely and well has the quaint Franciscan friar put it, "A little philosophy inclineth men's minds to atheism, but depth in philosophy bringeth men's minds about to religion, for, while the mind of man looketh on causes scattered, it may sometimes rest in them and go no farther; yet when it beholdeth the chain of them confederate and linked together, it must needs fly to Providence and Deity."

While, with Plotinus, not unmindful that it is not well of any man that he maintain over-earnestly that anything is known, yet it may scarcely be denied that, to the uses of the senses, things are what to the senses they seem to be,—a proposition in part Berkeleyan, but in much greater degree Cartesian. That matter and force exist as entities, says, wisely, the learned Prof. McCosh, is an intuitive recognition of every human mind. Three entities are there, teaches the philosophy of Descartes: Soul, Force, Matter,—at least this it teaches, if not exactly in these words. The physicist is necessarily a Cartesian, for if he start not out with such pre-

mises he finds himself quickly enough brought to it. Accepting the data of the Frenchman, or even that of Spinoza, all things grow plain to the understanding as it exists and recognizes; while confusions of all and every kind disappear as mists before a morning sun. To be a Cartesian is to be wise in the wisdom of one generation,—is to be without doubt or mystification,—is to be happily simple with the faithful, immobile with the Socratist.

Phenomena, asserts our author, cannot be what they appear, inasmuch as waking or sleeping we may seem to see the same things; hence, if these be true in the one instance, they may not possibly be so in the other. There the fallacy lies, in a non-recognition of the distinction between soul and mind.

We cannot endorse the convictions and conclusions of Mr. Andrews. Yet we have to thank him for a meditative hour, begotten of his little book, which, coming on the heels of a professional vexation, causes us to think most kindly of his effort. J. E. G.

GLEANINGS FROM OUR EXCHANGES.

REDUCTION OF HERNIA (*The Lancet*, April 25, 1874).—Dr. Edward Warren, chief staff surgeon to the Egyptian army, details a case of strangulated hernia relieved by taxis, and asserts that—1. A very large majority of hernial tumors, especially of the inguinal variety, can be reduced by manipulation, and do not demand the operation of herniotomy. 2. Manipulation should be practised deliberately and thoroughly, giving time enough to the work to determine the question of its feasibility, and, while fearlessly resorting, if necessary, to more than gentle pressure, cautiously avoiding the opposite extreme of roughness and violence. 3. As a general rule, the knife should be the last resource of the surgeon.

In regard to position he says, "When reduction is attempted without chloroform, the patient should be made to stand, with his head and shoulders bent downwards and forwards, and the spinal column inclined towards that groin in which the tumor exists; at the same time the weight of the body should be thrown upon the foot of the unaffected side, and the other foot placed somewhat in advance of its fellow. Should the effort prove fruitless, the patient may then be placed either upon his back, in the usual position, with a pillow under the buttock of the side corresponding with the hernia, and the head and shoulders inclined as before; or in a semi-prone position upon his hands and knees, with head depressed and pelvis elevated, as in certain operations upon the rectum and uterus."

Of auxiliary measures, chloroform is the most important; warm baths are of little use, and tobacco enemata are worse than useless. A good plan is to unload the lower bowel with an enema, inject morphia under the skin near the constriction, and then unexpectedly apply a cold douche to the abdomen, pushing in the gut at the same time.

TRANSFUSION OF BLOOD.—In the first number of the new German surgical journal, the *Centralblatt für Chirurgie*, we find that Dr. Tabouré, of St. Petersburg, has made twenty-eight different experiments on dogs. In the first eleven cases blood of various kinds of animals was transfused, in all cases defibrinated. The blood of dogs was transfused in two cats, and in seven dogs the blood of calves was transfused; cat's blood was thrown into one dog, and dog's blood into a sheep. In two cases, in dogs, death took place from twenty to twenty-two hours after transfusion of calf's blood, and the author in one case attributed the death to paralysis of

the heart, whilst in the second there was œdema of the brain and lungs. In all the rest of the cases the transfusion of defibrinated blood by different species of animals was not only well borne, but it gave the animals strength, like the blood of their own species. The author found the foreign blood to be assimilated in from twenty-four to sixty hours.

In eight cases, again, the leg of a dog was amputated, and great anæmia was caused. In the space of from ten to thirty minutes after the amputation defibrinated blood from calves or sheep was injected. In all cases death was the result from hemorrhage from the stump. Of two dogs which had blood transfused into them twenty-four hours after amputation, the first outlived the operation, whilst the second died on the eleventh day of acute purulent œdema and of septicæmia. In one case transfusion of defibrinated calf's blood was made two and a half days before the operation, and it got well in twelve days.—*The Doctor*.

THE THEORY OF COUNTER-IRRITATION (*The Practitioner*, March, 1874).—Dr. James Ross defines counter-irritation as the application of an irritant to one part of the body in order to influence morbid action in its vicinity. He believes that a counter-irritant always tends to stimulate the neighboring textures to increased activity, and that this stimulating action spreads along the parenchyma, not merely when the tissues are continuous but also when they are simply in contact. The question arises, Does the area of tissue stimulated to increased nutritive activity extend far enough, and in a sufficiently short time, to account for the action of counter-irritation? We can easily conceive that it does when we remember that Dr. Beale has found that if one has only a slight catarrh the bioplasm over the entire body is increased, and also recall the fact that a condition of unstable equilibrium exists between a diseased organ and the rest of the body, the former being much more readily influenced than usual. Dr. Ross says that this theory gives complete unity to our conception of the mode of action of counter-irritants.

IMPOTENCE CURED BY LOCAL FARADIZATION (*New York Medical Journal*, April, 1874).—A gentleman forty-six years of age, who was living with his second wife, had suffered for twelve months from impotence, which, though not absolute, was very annoying and alarming, and had produced a depressing effect on him. Both desire and power were deficient, but not destroyed. The emission occurred too soon. Treatment was commenced by local faradization, by various external applications, and in six weeks he was completely and permanently cured.

RELATIONS OF COLORADO TO PULMONARY CONSUMPTION.—Dr. Thomas E. Massey, of Denver, says that, while there are hundreds of living facts demonstrative of the curability of phthisis in Colorado, there are none to prove that those cures have been effected by any thermometric influences. He believes that the adjuncts of cure in Colorado are distinctly those of nutriment; the outdoor inspiration of pure mountain sunlit air depurating the vital current and stimulating the organs of primary digestion to receive and dispose of the nutritious animal food of the mountain-ranges.

QUININE IN HAY-FEVER (*The Practitioner*, April, 1874).—Professor Binz publishes a letter received by him from a gentleman who had suffered for twenty-one years from hay-fever, which invariably attacked him in the spring. He began to use weak injections of quinine, with the view of profiting by its poisonous action on any infusoria which might be present, but he obtained immediate and almost complete relief. He employed a neutral solution (1-800) of sulphate of quinia.

CHLORAL AS AN ANÆSTHETIC DURING LABOR (*The Lancet*, February 21, 1874).—Dr. W. Playfair has found that chloral has the immense advantage over chloroform, when administered during labor, of not lessening the strength or intensity of the pains, while at the same time markedly diminishing the suffering resulting from them. It is chiefly applicable at a period when we would not think of administering chloroform,—towards the termination of the first stage of labor, before the complete dilatation of the os and when the sharp grinding pains perhaps produce more suffering and are less easily borne than the more forcing pains of a later stage.

He gives the drug at first in fifteen-grain doses, and then in smaller quantity, increasing the intervals between its administration, and thus usually keeps up a full and sufficient effect for hours. It need not at all interfere with the exhibition of chloroform.

OZONE (*American Journal of Pharmacy*, April, 1874).—Mr. Sigismund Beer suggests that the exposure to atmospheric action of common phosphorus matches moistened by water will produce nitrite of ammonium and ozone, both active purifiers of air. He claims that in the use of matches in this way we have a handy, wholesome, and inexpensive means of disinfecting and purifying the air.

MISCELLANY.

HOW TO MAKE COFFEE.—The virtue of coffee consists in its volatile aroma and its fixed extractive matter. The happy combination of these with hot water is the problem for the coffee-maker. This happy combination, in my opinion, when realized in perfection, implies that all the aroma and all the extractive matter of the ground coffee be got into the hot water, and retained there. It seems to me that no argument is required to show that any aroma which escapes into the air, or any extractive matter left in the grounds, is so much virtue wasted. Now, to get at the same time the whole of these constituents of coffee has seemed very difficult. If boiling water be filtered through ground coffee—this is the French plan—the aroma is promptly extracted, and very little else, for the fixed matter needs more coaxing. If the grounds be boiled a long time in water—the Turkish and more common American plan—the aroma escapes with the steam. The French waste the extractive matter; the Turkish the aroma. I take rather more than the usual amount of coffee, and pour on it hot water when it is ready to be used; in other words, I make French coffee. The grounds from this operation I leave to soak in the pot till the next day, when I begin coffee-making by pouring hot water on these grounds, which hot water I use according to the French plan in making coffee from fresh-ground coffee. The process is now in full operation, and every time coffee is wanted the manipulations of the second morning are repeated. I thus extract all the soluble and useful matter of roasted coffee, and waste nothing. To put the art in the most practical form, I have found it necessary to modify the coffee-pot. Perhaps the simplest apparatus is the most ordinary pot provided with two strainers. The strainers are of cup form, and fit into

each other and into the top of the pot. For use I set a strainer on the top of the pot, and into the strainer I place fresh-ground coffee; over this I use the second strainer, containing the grounds of the last operation. Now hot water is poured into the upper strainer, and percolates down into the pot, carrying with it all the goodness remaining in the grounds, and the aroma and much of the extractive of the fresh-ground coffee. When the water has passed down, I throw away the now useless contents of the upper strainer, and upset the contents of the lower strainer into the pot.—*Professor Charles A. Seely, Journal of Applied Sciences.*

CASE OF MUSHROOM-POISONING.—Mr. Sadler, who was to have lectured to the North British branch of the Pharmaceutical Society in Edinburgh, was prevented from doing so by the following rather singular circumstance. While preparing for the Society his lecture on edible and poisonous fungi, he accidentally swallowed a quantity of the spores of a large species of puff-ball (*Lycoperdon giganteum*), and within the space of an hour and a half he was seized with severe illness, accompanied with violent pains. The violent symptoms could not be subdued until nine days after the first attack, by which time the patient was much weakened. Sir Robert Christison, Dr. Balfour, and Dr. William Craig, who have attended Mr. Sadler, are of opinion that the continued irritation was kept up by the fungus-spores. Mr. Sadler, though now in a fair way of recovery, is still confined to bed. The giant puff-ball is edible in its young state, but its matured spores ought certainly to be avoided.—*British Medical Association.*

USES OF THE YUCCA.—The root-stock of all the Yuccas is, under the name of "Amole," an important article in a Mexican household, being everywhere used as a substitute for soap, as it is replete with mucilaginous and saponaceous matter, probably a substance analogous to the saponine of the *Saponaria* root. It is curious to learn that the negroes of the coast of Carolina repeatedly destroyed Dr. Mellichamp's carefully-preserved clumps of yuccas, in order to obtain the saponaceous root-stock. How may the knowledge of its quality have reached them? Perhaps from the West Indies.—*Journal of Applied Science.*

POWDERED MEAT.—Powdered meat is prepared by Dannecey, *pharmacien en chef* of the hospitals of Bordeaux, by finely chopping the fresh meat, spreading it upon muslin, and drying it rapidly in a current of air. A friable mass is formed, which readily yields a brown, nearly odorless powder, possessing a feeble saline taste, and of which one part represents five parts of fresh meat. It is used and readily taken by patients by adding a teaspoonful to a cup of beef-tea or soup, or by spreading upon bread. For children it is mixed in certain proportions with the ingredients for biscuits.—*American Practitioner.*

OPIUM-ANTIDOTES.—In the *Peninsular Journal of Medicine* for April, Dr. A. B. Prescott shows that the "opium-antidotes" of Dr. Squire and of Dr. Collins are simply preparations of morphia.

CASTOR OIL VERSUS LEATHER.—A correspondent of the *Germantown Telegraph* states that after an extensive trial he has found castor oil much superior to all other fats and compounds as a preservative of leather, and the editor of the *Druggist's Circular* endorses the proposition.

RECENTLY, in Fall River, a jury awarded a lady, who had been almost fatally poisoned, \$15,000 damages; the defendants being a wholesale house which had sold a wrongly-labelled drug to the retailer of whom she had purchased. An appeal was taken to a higher court.

It is announced that Prof. Cohnheim is so much better that he will resume his duties at Breslau; also that Von Recklinghausen has finally accepted the position recently held by Prof. Rokitsky.

ALIZARIN is suggested as a substitute for litmus, and it is said to be about ten times as delicate in its reactions.

DR. W. P. ARMSTRONG advises rhus tox. (homœopathic) for "itching of the bones."

NOTES AND QUERIES.

INAUGURATION OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

The inauguration of the Hospital of the University of Pennsylvania took place on the 4th instant, with appropriate ceremonies.

A large number of the friends of the University, including various clerical, judicial, and lay celebrities, were present, as well as many ladies. An opening address was made by his excellency, the Governor of the Commonwealth, in the lower hall of the building, and two tablets fixed upon the walls of this hall not far from the main entrance were erected. The first of these contains the following inscription: "This hospital was erected through the liberality of the State of Pennsylvania, City of Philadelphia, and many citizens."

On the other is inscribed, "Inaugurated June 4, 1874, by his excellency John Hartranft, Governor of Pennsylvania."

After a banquet, the assembly adjourned to the larger lecture-room, where an admirable address was delivered by the Hon. William A. Wallace, of the State Senate, a firm friend of the institution, and to whose efforts were largely due the appropriation granted by the legislature. The address comprised a succinct history of the inception and carrying-out of the enterprise, and was listened to with great interest. At its close the company dispersed through the building for the purpose of inspecting it, while an orchestra supplied entertainment in the shape of a number of agreeable selections. The whole afternoon passed very pleasantly, and with these simple ceremonies was inaugurated an institution which will doubtless exercise a marked influence on the future of the University to which it is attached, and also on the progress of medical science in this country.

Various accounts of the architectural characteristics of the building have appeared from time to time in the daily papers, but there are some points of interest to medical men which may be mentioned.

The plan of the hospital includes a central building of administration, with a series of pavilions, six in number, and calculated to accommodate when completed at least seven hundred patients; of these the central building and one pavilion are completed, giving accommodations for one hundred and eighteen patients. The central building contains kitchen, apothecary-shop, steward's apartments and offices, and in addition, rooms for private patients, resident physicians, etc.

Two admirable lecture-rooms are contained in this part of the building: a smaller one on the first floor, which will accommodate two hundred students, and an amphitheatre, having its base in the second story, sixty feet in diameter, and forty-five feet high to the skylight in the centre of the ceiling, which is furnished with a dome. It will seat over five hundred persons. The main building is separated from the pavilion by a fire-proof corridor, preventing all possibility of the communication of fire from one portion of the structure to another. The basement of the pavilion is occupied by a series of apartments, or rather suites of rooms, intended for the

accommodation of the out-patient department. Each suite consists of a waiting- and a consulting-room, supplied with the necessary conveniences.

The medical and surgical dispensaries, the eye- and ear-, the skin-departments, etc., are entirely independent of each other.

There is also a general waiting-room connected with the apothecary-shop. On this floor are the rooms in which baths of various kinds will be placed for the treatment of different forms of disease, and also apparatus for the disinfection of clothing. The baths, when completed, will form probably the most complete system yet devised, comprising the various varieties of Turkish, Persian, continual, needle, vapor, douche, mercurial, etc.

The first and second floors contain each a larger and a smaller ward, the former accommodating thirty-two patients, the latter ten each. The third story will contain a ward for twenty-four beds. Connected with each of these wards is a series of admirably arranged bath-rooms, water-closets, sitting-rooms, convenient rooms for nurses, kitchens, and dining-rooms. As regards the arrangement for ventilation in the wards, it is perhaps not too much to say that it has never been surpassed in any similar institution. Twenty-four large windows are placed opposite one another, while a series of Barker's ventilators are arranged at the head of each bed, and comprise such a combination of heater and ventilator as to insure a plentiful supply of fresh air at a regulated temperature, while the colder foul air is carried off by a current created in the ventilating flue. Besides these, there are in each ward four large open fireplaces.

The whole building is plentifully provided with such labor-saving apparatus as bells, speaking-tubes, and dumb-waiters. One vertical railway or lift is of such size that a bed may be placed upon it, and patients raised or lowered to the various floors, as desired.

Besides the various baths, general and special, connected with the different wards, there are movable bath-tubs which are capable of being brought in immediate proximity to the patient's bed, and are likely to prove extremely useful in fevers and other cases where the application of water may be indicated.

When the buildings connected with the Hospital are completed, they will include, in addition to the ones already erected, certain others devoted to the study of physiology and pathology; the whole providing for not only the cure, but the study, of disease, with a completeness which it is believed has not heretofore been attained in this country, and which augurs most favorably for the future of our city as a "medical centre."

The cost of the structure has been in the neighborhood of \$200,000, which has been given by the State, while the six acres of ground on which it is situated is a gift of the city. For the support of the hospital, some \$350,000 has been raised by private subscription; and for the \$200,000 which is still necessary to place it on a proper footing in this respect, the Trustees appeal with confidence to the alumni and other friends of the University of Pennsylvania.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

In your issue of May 30, 1874, I noticed an abstract copied from the *London Lancet* which calls for a word of correction. It is headed "Elephantiasis Græcorum," but it is very manifest from the description of the case that quite another disease is meant,—namely, Elephantiasis Arabum. E. Græcorum is a term synonymous with leprosy, while E. Arabum is the name universally employed to describe the affection referred to in the abstract.

Respectfully yours,

ELEPHANTIASIS.

We have been requested to warn our city readers against a gentlemanly man who insists upon writing notes in the office during physicians' absence, and pockets whatever he may find of value.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 2 TO JUNE 8, 1874, INCLUSIVE.

BAILY, E. J., SURGEON.—Assigned to duty as Medical Director of this Department. G. O. 7, Department of the Columbia, May 20, 1874.

COOPER, GEORGE S., SURGEON.—Relieved from duty as Medical Director, and to report to Commanding General, Department of California. G. O. 7, c. s., Department of the Columbia.

WILLIAMS, J. W., ASSISTANT-SURGEON.—To report to Lieutenant-Colonel G. A. Custer, 7th Cavalry, for duty with Black Hills Expedition. S. O. 111, Department of Dakota, June 1, 1874.

STEINMETZ, WILLIAM R., ASSISTANT-SURGEON.—Granted leave of absence for three months. S. O. 120, A. G. O., June 1, 1874.

SATURDAY, JUNE 20, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE TERMINATIONS OF PNEUMOTHORAX; ESPECIALLY ON ITS TERMINATION IN RECOVERY.

Delivered at the Pennsylvania Hospital, November 15, 1873.

BY PROF. J. M. DA COSTA,

One of the Physicians to the Hospital.

Reported by EDWARD W. JAMESON, Resident Physician.

THIS morning I propose to bring before you some cases of pneumothorax, and to call your attention to the different modes in which this malady may terminate. Particularly shall I dwell upon some points connected with a favorable ending, and show you how the accumulation of air in the pleural sac, which is the essence of this grave malady, may pass away. The patient now before you illustrates some striking facts connected with the subject. Let me present the main features of his case.

Robert T., 21, single, a teamster by occupation, was admitted into this hospital October 21, with the following history: Driving his wagon while in an intoxicated condition, he fell from his seat and was run over, the hind wheels passing over his chest. The wagon was not loaded at the time, and at first he experienced no pain.

On admission, he was sent to the upper surgical ward. He was still under the influence of liquor, and was spitting up small quantities of blood mixed with saliva. He did not cough. No fracture of the ribs could be detected, and the only injury found was an abrasion over the right scapula. The next day the patient said he felt better, had neither pain nor cough, and the hæmoptysis had ceased.

Two days afterwards he began to cough, and expectorated rusty sputa. There was fever in the morning, and in the evening his pulse was 116, and temperature 103°.

On the fourth day after coming to the hospital he was admitted to the medical ward, and this was his condition: "Tongue pale, and covered with a light white fur; appetite poor; some fever; urine normal. On deep inspiration he complains of a pain in the right side, on a line with the axilla. On percussion, a tympanitic note is elicited anteriorly and posteriorly at the upper portion of the right side of the chest. At the base there is dulness, which changes with the position of the patient. Amphoric respiration is heard under the right clavicle and at the inferior angle of the scapula. The breath-sounds are distant. The amphoric voice is well heard. On placing the ear against the chest, and shaking the body, succussion is distinctly perceived. There is constant hacking cough, and he has expectorated a small coagulum of blood. He was ordered pills of quinine, digitalis, and opium.

Gentlemen, you have heard me read the notes of this case prior to its coming into my hands. A few days after taking charge of it I was struck with the fact that no succussion existed, and that the amphoric respiration and percussion had disappeared.

They have not been re-developed; the patient is gaining flesh and color; his breathing is no longer labored, and there is a marked change in every respect for the better.

A physical examination to-day finds the right chest larger and fuller than the left. When he breathes, although the right side moves, it does not move so freely as the left. Inspection shows the intercostal spaces on the right side effaced. The percussion-note anteriorly on the right side is clear, except over the lower part of the lung, where from the nipple down dulness is perceptible; no material difference exists anteriorly at the upper part between the two sides; the right side is, however, of lower pitch than the left. Posteriorly, over the upper and middle of the right lung the percussion-note is clear, but approaches to a tympanitic sound, yet not so markedly as four or five days since; lower down there is dulness.

Auscultation over the right side anteriorly shows the respiratory sounds decidedly feebler than over the left side. A few fine friction-sounds are heard at the upper part of the lung both anteriorly and posteriorly on the right side; the respiration at the lower part of the lung is absent; the vocal vibrations are much more distinctly perceptible over the left side. There are not on either side succussion-phenomena or râles. The action of the heart is rapid, the pulse quick and somewhat jerky.

This is undoubtedly a case of pneumothorax ending in recovery. Indeed, when we see that our patient now is up and dressed, it is evident that he also is regaining his strength. Nor will it be necessary to continue the pills of quinine, digitalis, and opium long; a mixture consisting largely of iron with acetic acid and acetate of ammonium will take their place, and act more efficiently the part of a tonic.

There are many points about the case that I could call your attention to, and especially several connected with the development of the trouble. But the great interest consists, after all, in the disappearance of the signs of pneumothorax, and in the striking improvement in health which went hand in hand with the disappearance. The air must have been absorbed, and the spot of puncture of the lung healed. There is still some fluid in the pleural sac, but it is much diminished, and everything betokens a complete return to health.*

Now, this illustrates one form of recovery,—a speedy recovery, too, in which the absorption of air has been rapidly followed by the absorption of the small quantity of fluid that existed. Such cases are, on the whole, not very frequent, yet you will meet with them every now and then. Some years since, I saw with my colleague, Dr. John F. Meigs, and with Prof. Stillé, one quite as striking, and similar in many respects, excepting in its origin. It occurred in the person of an iron-master, about fifty years of age, most extensively and laboriously engaged. He noticed that without any very evident reason he was

* When the patient left the hospital, December 22, he was looking well and strong. The signs of effusion had all but gone; the respiratory murmur over the lower part of the lung had become distinct.

unable to exert himself actively; indeed, exertion made him short of breath, which he attributed to being weaker than usual. Coming to the city, Dr. Meigs found the cause of the waning strength to be a right-sided pneumothorax; but how it had happened could not be definitely ascertained. There was neither tubercle nor emphysema, and the only clue to the case was that several weeks before the dyspnoea was noticed the patient had had a severe cold, attended with cough and oppression, which might have been a latent pneumonia. The physical signs of pneumothorax were certainly most marked: the cough and voice and breath-sounds distinctly metallic; succussion-phenomena did not, however, exist. The liver was displaced, but there was no pleuritic effusion, or this was so slight that its very presence was doubtful. In the course of a few months, under rest and tonics, the air in the sac vanished, and I heard recently that our patient was in vigorous health, and had remarried. In this case, of which we may say that it was a pure one of pneumothorax, the air was absorbed, rest and tonics, as in the preceding case, favoring the favorable issue.

But there are cases which form, as it were, a group by themselves, in which the pneumothorax proper passes away, but in which the disorder terminates in chronic pleurisy, having all the chances and complications, and requiring the treatment, of this affection. The following instance, which came under my observation some years ago, is a case in point. A young man, 22 years of age, in seeking relief for his dyspnoea, stated that while heated and perspiring freely he was subjected to drafts of cool air, and soon afterwards found himself with a cough which had never left him. About four months afterwards he was seized with pain in the left side, and with difficulty in breathing. When he presented himself to me he was pale, thin, had a cough, with thin mucous expectoration, a pulse rapid and feeble, and constant and troublesome difficulty of breathing and pain in the left side. Physical examination showed that the left side of the chest was more prominent than the right, and anteriorly at the upper portion the intercostal spaces were effaced. The left side from the ensiform cartilage to the vertebræ measured nearly three-quarters of an inch more than the right side. Percussion proved the right side to be clearer, while the left side was extremely dull at the lower middle portion anteriorly and posteriorly. Auscultation on the right side anteriorly showed a loud and harsh sound; the expiration at the apex was distinctly prolonged. On the left side, at the upper portion, there was a friction-sound in expiration, but no vesicular murmur; occasionally the ear caught a metallic tinkle and a metallic whiff of respiration, especially in expiration. At the posterior edge of the scapula there was metallic respiration with distinct metallic tinkling. The voice had a metallic ring at the same spot; the fremitus was not increased, perhaps decreased. The vocal resonance anteriorly was feeble. At the posterior portion lower down, voice and respiration were absent. No splashing sound was heard.

I saw my patient from time to time, and found him gaining strength and flesh; his breathing by degrees became easier, and the physical signs improved,—that is, the metallic phenomena were not so marked.

His condition, under the use of iron, iodide of potassium, and cod-liver oil, remained satisfactory for some weeks, and I did not see him until, visiting me again, I found that on percussion on the left side there was flatness from the clavicle down, and over the whole of the left lung posteriorly the same absence of resonance existed. The right side was clear. Inspection showed the heart beating on the right side, pushed considerably over the right edge of the sternum. Auscultation made apparent that the inspiration all over the right lung was distinct, even somewhat harsh; the expiration was prolonged. On the left side, anteriorly, the respiratory sound was nearly absent; between the second interspace towards the sternum an occasional whiff-like amphoric breathing was heard, and at a point posteriorly nearly corresponding to the middle of the scapula this same sound was heard, only more blowing and less amphoric. At the upper portion of the lung the voice was distinct, but not so much so as on the right side, although it was slightly more concentrated. The vocal fremitus was stronger all over the right lung.

In the course of some weeks all the amphoric phenomena had disappeared, and the case had become one of chronic pleurisy with large effusion. The most troublesome symptom was difficulty of breathing, and although the general condition continued to improve, this did not. The operation of paracentesis was urged, but declined. My patient now left the city. After losing sight of him for two years, he presented himself with the statement that since last examined he had been living in Connecticut, and had been working steadily, and although on severe exertion he had not been able to breathe freely, yet he had been generally in good health up to three or four weeks prior to his return, when, after a by no means hard day's work, he was seized with chills and a cough, which he attributed to checked perspiration. He was weak, and on listening to his chest I found there were râles in both lungs, especially audible over the right. In the left a most peculiar sound was heard: it resembled a double blowing sound of high pitch, but was metallic, and did not stop when breathing stopped. It seemed to be produced by the action of the heart; yet there was no murmur in the heart, nor was this sound constant. Lower down, the respirations were very feeble, hardly audible. There was dulness on percussion posteriorly low down, also at the inferior lateral portions of the chest; the note was clear above.

The heart was precisely at the right side of the sternum; there was no succussion-sound, but rattling sounds were audible on breathing, even when the ear was not placed to the chest. He was expectorating a great deal. At several examinations made subsequently, distinct metallic breathing and tinkling were perceived near the inferior angle of the left scapula, and signs of tuberculosis of the right

apex, and of softening at the left, became manifest. Still later in the case the physical signs changed again. There was dulness on percussion *all over* the left lung, beginning very high up anteriorly; the amphoric sound, the râles and metallic tinkling, had disappeared. It was evident that the effusion had again increased. The difficulty in breathing was now very great; the expectoration amounted to but little. The feet began to swell, and night-sweats were frequent and exhaustive. The dropsy increased, and the patient died, exhausted. His illness had lasted upwards of three years.

Now, I shall not attempt to explain to you at length the phenomena of this remarkable case. We may, I think, assume that the patient had at first a latent pneumonia, followed by giving way of the lung and pneumothorax; that either just prior to this, or soon afterwards, he became tubercular, and that though the tubercular trouble never assumed any activity until late in the case, it finally much hastened the fatal ending.

But I pass by these points, as well as the interesting fact that the metallic phenomena were at times developed by the action of the heart, to recall how the case of pneumothorax terminated in chronic pleurisy; how the opening through which the lung and pleura communicated must have been closed; how comparatively well the man was for several years; how, finally, the same spot at which the original injury took place must have reopened, or one near to it have given way; and to note the curious way in which the signs of pneumothorax again disappeared, suggesting that the second break had been closed, and, most likely, also in the same manner by the exudation resulting from the inflammation of the irritated pleura.

You can easily understand, also, how in a case of the kind, provided the fluid can be evacuated, and no other trouble lie back of the chronic pleuritic effusion, a complete recovery may happen.

Let me now call your attention to a third mode of termination: not one that can be exactly called a recovery, yet one in which the patient remains for a long time in fair general health, while the signs of pneumothorax persist.

I shall never forget my astonishment at the first case of this nature I saw,—that of a lawyer, who from his history had evidently had the malady for nearly a year, and in whom the shortness of breath was the only annoying symptom,—when I found the most marked signs of pneumothorax in examining his chest, including succussion and metallic tinkling.

Since, I have seen similar instances of what I may call chronic pneumothorax; and it is astonishing how well some of them have done, and how the breathing-powers have accommodated themselves to the anomalous state of things.

But sooner or later, unless the opening in the lung closes, and the disorder enters, therefore, into the second category discussed, it terminates fatally, and usually by gradual exhaustion. And if you ask me whether, from experience, I can tell you of any general law by which you may suspect that the case has ceased to do well, I answer that I believe

that the accurate appreciation of *the quickening of the respiration, and especially the marked quickening of the action of the heart*, is that general law.

Having now explained to you the terminations of pneumothorax in recovery, or at least in conditions favorable to the prolongation of life, I will show you the specimens obtained from an instance of tubercular pneumothorax recently in the ward, and will, in reading you the history, tell you of the means by which, while they did not avert the unfortunate issue, considerable relief was afforded:

"Charles W., 40, married, carpenter, free from venereal taint, a sober, industrious, hard-working man, whose parents died of phthisis.

"His wife relates that he had more or less cough since last summer, but was never laid up until eight weeks before admission. About that time, while working at his trade, he was exposed to two rain-storms. This increased his cough, and his expectoration was more abundant. He had muscular pains, and felt much indisposed. Two weeks later he fell off a 'board-float' into the river, and the effects of this, added to his previous unwell state, laid him up.

"His symptoms were repeated chilliness, followed by fever, languor, general weakness, loss of appetite. His sputa were yellow, and abundant, but of late he has expectorated but little. Has never had night-sweats; but lays stress on the fact that his breathing grew 'shorter and shorter.' While sick he had good attention, and the impression was that he had inflammation of the lungs.

"On the day before Christmas he thought himself able to work during the sunny hours, and made the attempt, but found himself too weak and short-breathed to continue on.

"On admission, the patient looks anæmic; he is very weak; his respirations are labored; decubitus is on the right side, with the shoulders rather elevated; there is little or no cough.

"Temperature 99°; pulse 110; respiration 40; urine high-colored, acid, specific gravity 1.028, non-albuminous.

"Physical signs—metallic cough and respiration, and comparatively imperfect succussion at the lower portion of the right lung posteriorly. Of all the phenomena the metallic-ringing cough is the most distinctive; percussion note is tympanitic from the upper part down posteriorly, not markedly so at apex, though here even more than at the apex of the left side.

"He was ordered tincture of cannabis indica, gtt. xx every third hour, quinine, gr. x daily, brandy, and beef-tea.

"A few days after admission, his pulse was 112, temperature 98°, respiration 60.

"There was crackling with coarse respiration posteriorly, left side, and at middle part anteriorly, and towards the sternum was distinct metallic respiration, especially at the left edge, and transmitted across from the right side. The heart was pushed over to the left axilla. The other signs present on the day of his admission were unchanged. The patient was covered with beads of sweat, laboring hard at each inspiration, and, as the difficulty was increasing, aspiration was decided on. The entrance to the chest was effected posteriorly, between the fourth and fifth ribs, over the point of greatest tympanitic resonance and amphoric breathing. As soon as the cavity of the chest had been entered, air rushed out with a whistling sound; the aspirator was applied and pumped for a few minutes, when a yellowish fluid, of creamy consistence, showed itself, and was drawn off to the amount of nearly one quart.

"The operation gave him much relief, and his expression was that a great load had been taken off his chest. The respiration was more free, less labored, and he sat up in bed more comfortably than before the operation.

"The relief, however, was but temporary, and the patient died forty-eight hours after the operation."

The specimens which here lie before you were removed some eleven hours after death. It was noted that the emaciation was not marked, and that the thorax on being opened allowed of a free escape of air. The right lung, you notice, is collapsed, and the pleura on both its costal and its pulmonary surface is covered with a thick layer of tough lymph.

The lung is reduced in size, and there is a large cavity in its upper lobe, while the lower lobe is filled with cheesy masses.

The left lung is somewhat torn, due to the adhesions which existed posteriorly and at its apex; the upper lobe is infiltrated with the same cheesy masses as on the right side, only more firm, perhaps, though some to the touch feel quite soft.

The pleura on this side looks to be covered with very minute miliary-looking bodies, which appear almost like granulations; yet to the touch they feel as if immediately beneath the surface.

The serous membrane of the heart is covered, here and there, with lymph, and a few bands exist between the opposing surfaces, but these are readily broken down. Aside from the liver, which is enlarged and somewhat congested, the other viscera look normal.

In this case, you see, I employed *cannabis indica* first, and from this I have known relief to the dyspnoea, but the harassing symptom was far more influenced by the use of the aspirator; and, in conclusion, I call your attention to the value of this instrument in assuaging the distress of cases in which you are forced to despair of a cure.

ORIGINAL COMMUNICATIONS.

ON LIGATURES: AN ATTEMPT TO DECIDE ON THE BEST MATERIAL FOR THE LIGATION OF ARTERIES.

WITH EXPERIMENTS.

BY JOHN R. HAYNES, M.D.,
Philadelphia.

(Concluded from page 568.)

ANIMAL LIGATURES.

IT has long been the hope of surgeons that some form of ligature might be obtained which could be left in the wound without creating suppuration, and over which union by first intention might take place. We have seen how the advocates of short silk ligatures were disappointed by the results of experience: finding that disturbance of some sort almost invariably ensued from their use. During the present century a series of ligatures composed of various animal tissues has been brought into notice, under the belief that the peculiarity of their composition would not only

render them innocuous, but would also lead to their absorption, and thus prevent all chance of their acting as foreign bodies. Hence it was supposed that union of wounds by adhesion would occur much more frequently than under the employment of the common silk ligature; for the latter was accused as the fruitful source of prolonged suppuration, and also (from the fact that in the process of extrusion it necessarily divided the artery) of secondary hemorrhage. The latter accident, it was further thought, would cease to torment both surgeon and patient, for it was confidently advanced that animal ligatures would not cause division of the artery, because of their speedy removal by absorption.

The celebrated Physick, to whom we are indebted for so many real advances in the art of surgery, was the first to employ the animal ligature in actual practice. He used strips of chamois leather, rolled into a round hard cord between two marble slabs. In 1813, Dr. Thomas Young, of Edinburgh, mentioned catgut as a substance worthy of trial for ligation of arteries,* and, indeed, we find proofs of the use of the same material for sutures in the writings of Rhazes (A.D. 900), and of Albucasis (who flourished about two centuries later). Notwithstanding these facts, no doubt exists that Physick, in 1814, originated the use of the animal ligature. Unfortunately, no record of the results obtained by him remain, although it is said that his example was followed by Dorsey.

Dr. H. G. Jamieson, of Baltimore, used ligatures made of strips of buckskin for a number of years. He never published a detailed account of his cases, but it is said that the ligatures were never known to come away, and that the wounds generally healed by first intention. In experiments on animals he found that buckskin ligatures were sometimes encapsulated and sometimes absorbed.†

Various other tissues have been employed: thus, Hartshorne, of Philadelphia, used strips of parchment, and Eve, of Kentucky, the dried tendons of the deer. Manec, of Paris, made trial of filaments of nerves and tendons, but found that the wound never healed by first intention without the subsequent extrusion of the ligatures.

In 1817, Cooper introduced catgut into practice. Porta, in 1845, published the results of his experience with this substance, and finally Lister, of Glasgow, in 1869, revived its use, and taught a peculiar method of preparing it.

CATGUT LIGATURES.

Experiments on Animals.—Sir Astley Cooper recites his experiment in the following words:

"I tied the carotid of a dog with catgut ligature [prepared by soaking in water at 100° F.]; in a fortnight after, I killed the animal, and found that the ligature had not been dissolved, but that it had cut its way through the artery, and was situated in a cyst like that which is found around a ball, between the divided ends of the vessel, in a quiescent state."‡

* Introduction to Medical Literature, Edinburgh, 1818, p. 424.

† Cooper's Surgical Dictionary, Amer. edit., art. Ligature.

‡ Cooper's Lectures, 1829, p. 168.

Porta made numerous experiments with catgut on the arteries of various animals. In eighty experiments to test the frequency of absorption, the ligature was absorbed in thirty-three instances, and in several others very much softened. In some cases it became encysted, or, becoming dry and stiff, "it was left bare in the layers of the cellular tissue." Occasionally an abscess formed, and the ligature was thrown off. Out of two hundred and thirty-six experiments to test the frequency of this occurrence, abscesses formed in twenty-six. "Catgut," says Porta, "differs from other ligatures, as it does not always divide the internal wall the moment the knot is formed, but, becoming lax by the process of softening, it sometimes allows the artery to reopen. This, however, does not interfere with the success of the operation when the relaxation is gradual, and the internal plug is formed in time."*

Experiments of the Writer.

Exp. XXIV.—The carotid of a cat was tied with non-carbolized catgut, and, one inch below, with carbolized catgut. The wound, which had been closed by a continuous suture of fine silk, healed by adhesion. In twenty-five days the parts were examined: no traces of the ligatures could be found. The vessel was occluded at and between the points to which they had been applied.

Exp. XXV.—The carotid of a cat was tied firmly with catgut (non-carbolized); the wound was treated as in *Exp. XXIV.*, and with the same results. When the parts were examined, forty-four days after, the ligature was found *in situ* around the remains of the artery; it presented no appearance of absorption. [See Experiments VIII., XIII., and XXII.]

Results of the Use of Catgut on Man.

Cooper, in 1817, tied the femoral of an old man, for popliteal aneurism, with catgut which had been soaked in warm water. The wound healed, without suppuration, in four days, and nothing was seen of the ligature. He subsequently employed catgut in three additional cases of aneurism, in all of which "it came away by suppuration and ulceration." From the result of these cases and the experiment related above, Sir Astley concluded that catgut ligatures were not at all superior to common ones, and abandoned their use.

Norman, of Bath, England, tried catgut in two cases of aneurism, but long and troublesome suppuration ensued in both instances.

Porta relates eleven instances of ligation of arteries in their continuity by catgut. In only one of these cases, an instance of ligation of the carotid, can the result be said to have been perfectly satisfactory. In no case was the ligature seen to come away, but the artery was found divided in all instances in which the patient died after a sufficient interval had elapsed.

Manec, of Paris, in some cases in which he tried catgut found that it was always extruded by suppuration in cases where union by adhesion occurred. No details of the cases are given.†

The following table gives all the recorded cases

in which catgut (non-carbolized) was used in ligating arteries in their continuity. In all the cases the disease requiring the operation was aneurism.

NO.	OPERATOR.	ARTERY TIED.	HISTORY OF THE CASE.
1	Porta. ^a	Carotid.	The patient did well, but the wound did not unite till two months had passed.
2	Porta.	Carotid.	Wound healed soundly and permanently in four days.
3	Porta.	Carotid.	Death in forty hours.
4	Porta.	Brachial.	The patient died in sixty-five days after operation, of pneumonia, "probably pyæmic." The wound had suppurated till death, but the autopsy showed this to be superficial.
5	Porta.	Brachial.	Wound did not close for a month.
6	Porta.	Femoral.	Wound suppurated until death, which occurred on the seventeenth day, from gangrene.
7	Porta.	Femoral.	Death in fifty-five hours.
8	Porta.	Femoral.	Death in ten days, from encephalitis. External wound healed, but small abscess found beneath fascia lata.
9	Porta.	Ext. iliac.	Death on the third day, from encephalitis.
10	Guerini. ^b	Brachial.	Wound did not close for five weeks.
11	Guerini.	Post. tibial.	Tumor laid open, causing a large wound, and catgut applied. Wound closed in six weeks.
12	A. Cooper. ^c	Femoral.	In this man, who was eighty years old, the wound was closed with adhesive plaster, and, when examined on the fourth day, was found perfectly healed.
13	A. Cooper.	Femoral.	"The catgut came away by suppuration and ulceration as in common cases."
14	A. Cooper.	Femoral.	
15	A. Cooper.	Femoral.	
16	Norman. ^d	Femoral.	The wound suppurated for six weeks. Ligature was not seen to come away, but operator thought it did.
17	Norman.	Femoral.	Very long in healing.
18	Crampton. ^e	Com. iliac.	Pulsation returned at fiftieth hour, and so far increased as to justify the suspicion that the ligature had softened and given way. On the eighth day the ligature, the ends of which had been left hanging from the wound (not cut short, as in the other cases), came away. On the tenth day, the man died in less than a minute, from hemorrhage from the distal end of the artery. On examination, internal and middle coats divided. An opening existed in external coat, which communicated with abscess. The operator observes, "It appeared that the ligature had been dissolved by the heat and moisture of the wound, and thrown off before the obstruction of the artery or the coagulation of blood in aneurismal sac had been completed. It further appeared that the dissolution of the ligature had caused a small abscess in the place which it occupied."

^e Crampton, Med.-Chir. Trans., vol. xvi. p. 163.

Professor Agnew used catgut (non-carbolized) in two cases of amputation at the Pennsylvania Hospital. In one, some of the vessels were tied with catgut, and some with silk. The wound pursued the ordinary course, and the patient recovered. In the second case, catgut alone was used; the man died of pyæmia.

CARBOLIZED CATGUT.

Preparation.—Lister directs that catgut be prepared by soaking it for at least four hours in an oily solution of carbolic acid (one part to five of olive oil to which a very small quantity of water

* Op. citat., pp. 21, 22.

† Lisfranc on the Obliteration of Arteries, Paris, 1832.

has been added). At the beginning of an operation the catgut may be transferred to water.

Mr. Lister advocates carbolized catgut very strongly for the ligation of arteries. He formerly employed it for sutures also, but has now abandoned it for that purpose; why, he has not informed us. Perhaps the almost invariable suppuration which followed its use as a suture, in the writer's experiments on the lower animals, may throw some light on this point. The ingenious inventor of the antiseptic system seems to base his support of this variety of ligature on the following experiment, for in no place has he published any cases bearing on the subject:

The carotid of a calf was tied with two ligatures of animal tissue at an interval of one-half inch, the sheath of the vessel being left intact between them. The cardiac ligature was a threefold cord, composed of strips of peritoneum of ox. The distal ligature was a double one of minikin catgut. Both ligatures had been soaked for four hours in a saturated watery solution of carbolic acid. The wound was brought together with copper sutures, and antiseptic dressing used. In ten days dressings removed, and wound found entirely healed. On dissection, in thirty days, the site of each ligature was occupied by a ridge continuous with the external coat of the artery. Under the microscope this was found to be composed of fibrous tissue. The author considers that these ridges were *the ligatures which had undergone organization*. The vessel was obliterated in and between the position of both ligatures.*

Experiments of the Writer with Carbolized Catgut.

The following was a repetition of Lister's experiment:

Exp. XXVI.—The right carotid of a goat was tied with a cord composed of three pieces of carbolized catgut, and one-half inch above, leaving the sheath intact between, with two pieces of "minikin" gut. Both ligatures had been soaked four hours in a saturated watery solution of carbolic acid; and, indeed, carbolic acid was used according to Lister's directions all through the experiment. The wound was closed with silver sutures. On the tenth day, the dressings were removed and the sutures taken out. The wound was perfectly healed. On the thirtieth day the parts were examined. The lesser ligature had disappeared, and the artery was not constricted at its site; a partially adherent clot occupied the vessel down to the lowest ligature, which had caused the walls of the vessel to be absorbed within its noose. A thin layer of organized lymph, continuous with the edges of the vessel, covered the sides of the ligature. Above the ligature, the vessel was not obstructed except by the clot just mentioned; below the vessel was entirely obliterated for some distance. The ligature itself was slightly swollen and softened.

Exp. XXVII.—A coil composed of eighteen inches of carbolized catgut was placed in the peritoneal cavity of a cat. On examination in seventy days no traces of the catgut were found except a few stained lines on the omentum.

Exp. XXVIII.—A coil composed of twelve inches of carbolized catgut was placed under the skin of a cat's shoulder, and the incision closed by sutures of the same material. It healed by first intention; on dissection in five days the catgut was found floating in pus.

Exp. XXIX.—A piece of carbolized catgut two inches long was inserted under the integument of a cat; was extruded by suppuration on the fourth day.

Exp. XXX.—The biceps extensor of a cat's leg was surrounded with carbolized catgut subcutaneously. No disturbance ensued, and on dissection in seventy-three days only a shred of the catgut could be found.

Exp. XXXI.—The carotid of a cat was ligated with carbolized catgut, and the wound closed with a continuous suture of the same material. Profuse suppuration ensued, and healing was not completed till the twentieth day. In thirty days a dissection of the parts revealed the ligature in exactly the same condition as when applied, encapsulated, and enclosing the remains of the artery.

Exp. XXXII.—Same as Experiment XXXI. The wound, which was closed with silk sutures, healed by first intention. On examination in thirty-two days the vessel was occluded, and no trace of the ligature remained.

Exp. XXXIII.—Same precisely as Experiment XXXI., with a like result.

Exp. XXXIV.—Same precisely as Experiment XXXI., with a like result.

Exp. XXXV.—Same as Experiment XXXI. Wound closed with carbolized catgut sutures; slight suppuration ensued. On dissection in sixty-three days, no trace of ligature; the artery was adherent to its sheath, and slightly indented at point of ligation. It was occluded for the space of one-sixth inch.

Exp. XXXVI.—The carotid of a cat was tied with carbolized catgut, and the wound closed with sutures of same material. "Antiseptic" dressings were applied. On dissection after six days pus was found flowing from the wound; the knot of the ligature projected into an abscess bounded by the sides of the wound. The noose of the ligature was surrounded by healthy tissue, and no sign of absorption existed.

Exp. XXXVII.—The carotid of a cat was tied in two places with carbolized catgut, and divided between the ligatures; the wound was closed by a continuous suture of fine silk, and healed by adhesion. On dissection after thirty-six days the ends of the vessel were found united by a band of organized lymph. The ligatures, surrounded by a thin capsule, were *in situ*, but barely visible from the progress of absorption.

Exp. XXXVIII.—The carotid of a cat was tied with a strip of bullock's peritoneum (not carbolized). The wound, which was closed by silk suture, healed by adhesion. In sixteen days the parts were examined. The ligature had entirely disappeared, except the knot, which was *in situ*. The artery was occluded.

Exp. XXXIX.—A piece of carbolized catgut (as thick as saddler's silk) was passed under a portion of the skin of the writer's arm, and the ends tied together externally. The parts were protected by adhesive plaster. On the eighth day one end of the catgut dropped off, and slight traction at the other end sufficed to bring away a portion of the gut that had been under the skin. This portion presented a nibbled and macerated appearance, and on taking it between the thumb and the finger slight pressure was enough to disorganize it. A drop or two of pus exuded from each orifice, and the track of the catgut presented to the finger the sensation of a hard band, as if it were occupied by lymph.

RESULTS OF THE USE OF CARBOLIZED CATGUT IN MAN.

The following table gives a short account of all the recorded cases in which arteries have been ligated in their continuity with this material:

* Lancet, April 3, 1869, p. 454.

NO.	OPERATOR AND REFERENCE.	AGE.	ARTERIES TIED.	DISEASES FOR WHICH TIED.	HISTORY.
1	T. Holmes. Lancet, 1872, p. 69.	50	Subclavian and carotid.	Innominate aneurism.	The vessels were tied tightly. Some small vessels in the subclavian wound were tied with silk. Continuous catgut suture was used. Dressing antiseptic for one day, when the patient disturbed the bandages. The carotid wound suppurated a little, but finally closed on the thirteenth day. The subclavian wound contracted to a short sinus, which remained till death, which occurred on the fifty-fifth day, from inflammation of sac. Autopsy.—“On the carotid, lying between it and vein, there was a lump something like a small gland, and the artery was constricted. When laid open, its calibre was found to be interrupted merely by a thin stratum of partly decolorized clot. A distinct ridge, or transverse mark, indicated the position of the ligature, and below this, between it and the heart, at about one-eighth of an inch distant, were two very minute apertures in the internal coat. One did not lead through walls of vessels; the other led into the small lump above mentioned, which was a mass of cellular tissue and debris of blood-clot, in which no ligature could be found, though carefully looked for. Nor was there a trace of the ligature in any other part. In the subclavian, also, there were no remains of the catgut ligature. This artery was not interrupted in its continuity in the place where it had been tied, but was completely closed by a diaphragm less than one-fourth of an inch thick.”
2	C. Heath. Lancet, July 27, 1872, p. 108.	48	Subclavian and carotid.	Aortic aneurism.	The wound was dressed with cotton-wool. When opened, on eighth day, it was found entirely and permanently healed by first intention. Patient improved greatly, and, after leading a very intemperate life for four years, died from bursting of the aneurism in front of the sternum. On autopsy, the tumor, which had been mistaken for innominate, was found to be entirely aortic.
3	Thomas Bryant. Med. Times and Gazette, July 27, 1872, p. 87.	33	Subclavian.	Innominate aneurism.	A large vein was wounded and ligated. On the fourth day, slight bleeding from the wound; checked by ice. On the fifth day the dressing (cotton) was removed. Wound discharging broken-down blood from only spot not healed.
4	Stocks. Liv. and Manch. Med. and Surg. Rep., 1873, p. 127.	42	Subclavian.	Axillary aneurism.	The artery was tied in its third part with a double ligature. Antiseptic treatment. On sixth day, bloody discharge from wound. Tenth day, wound slightly opened; no reparative action. Twelfth day, man died of asthenia,—probably septicæmia, though the author confesses that he cannot satisfactorily account for his death. Autopsy.—One lung partially solidified. The ligature had disappeared. There was a deep constriction in the artery at point of application. On opening the vessel, it was found that its coats had not been injured. A firm clot, one and a half inches long, filled the proximal side. On the distal side the tumor was close to the site of ligation.
5	Bernard. Am. Lancet, Sept. 1872, p. 482.	25	Common carotid (left).	Hemorrhage (from fauces).	Antiseptically treated. In nineteen days the wound was healed, except a small sinus, through which the knot of the ligature, as the operator supposed, was discharged. At the expiration of fifty-nine days there was still slight oozing from centre of wound.
6	Bernard. Op. citat., p. 481.	39	External iliac.	Femoral aneurism.	Antiseptically treated. In six days the edges of the wound were extremely inflamed: “almost sphaceloid.” The carbolic dressings were removed, and opiates applied. After thirty-nine days, thick, purulent matter still discharging from the wound. In fifty-three days, wound entirely healed. It is not stated whether or not the ligature came away.
7	Atchley. Lancet, April, 1870, p. 585.	41	Femoral.	Popliteal aneurism.	The incision “was quite healed by the twentieth day.”
8	James Spence. Lancet, June 5, 1869, p. 773.		Common carotid (right).		The ligature was tied with three knots. The patient did very well until next day, when, after taking a drink of milk, he vomited, then immediately became comatose, and paralyzed on the left side. Death ensued on third day after operation. On autopsy, it was found that the vessel was not constricted at the point where the ligature had been applied. Some loose, pulpy material was found. On examination, this proved to be the ligature, which had separated at a point opposite the knot. A large embolus obstructed the right middle cerebral artery. The author supposes that the vomiting caused rupture of the ligature, after which the clot was swept up by the blood-current.
9	Jessop. Lancet, Nov. 30, 1872, p. 776.	22	Brachial.	Traumatic aneurism at head of elbow, size of walnut.	The tumor was laid open, and the artery secured by means of two carbolized catgut ligatures, placed on either side of a minute opening at bottom of sac. Antiseptic treatment: “Wound healed directly,” and patient went home, cured, on twelfth day.
10	Lund. Lancet, August 5, 1871.	42	External iliac.	Femoral aneurism.	Antiseptic treatment. On eighth day, wound healed, except at one spot. No pus secreted. Twenty-sixth day, patient sitting up.
11	Watson. Ranking’s Abstract.		External iliac.	Inguinal aneurism.	The patient died nine weeks after, from hemorrhage. A silk ligature was applied to abdominal aorta, sixty-five hours before death. On autopsy, the external iliac was found completely divided, and nothing was seen of the ligature.
12	Nankinell. Lancet, Feb. 10, 1872, p. 187.		Femoral.	Popliteal aneurism.	Antiseptic treatment. Wound suppurated, and healed in thirty-one days. Nothing said of ligature coming away.
13	T. Smith. Lancet, Nov. 23, 1872, p. 741.	30	Femoral.	Popliteal aneurism.	Antiseptic treatment. Wound suppurated, and was not entirely healed after a month had passed.
14	T. Smith. Lancet, Oct. 13, 1872, p. 549.	40	Femoral.	Popliteal aneurism.	Antiseptic treatment. Eighth day, sutures removed; no pus. Ninth day, wound healed, except at lower part, where lint was inserted.

NO.	OPERATOR AND REFERENCE.	AGE.	ARTERIES TIED.	DISEASES FOR WHICH TIED.	HISTORY.
15	C. J. Gibbs. Brit. Med. Jour., Sept. 24, 1870.	35	Femoral.	Popliteal aneurism.	Antiseptic treatment. Eighth day, united by first intention, except that a slight superficial discharge existed, which continued fourteen days. Seven weeks after, man died of phlegmonous erysipelas of same limb. Autopsy.—Large mass of hardened lymph surrounded wound. The artery was "narrowed and compressed" at point of ligation. Its coats were perfect. Its calibre was obstructed by organized clot. No traces of ligature were observed.
16	Holden. St. Barth. Hosp. Rep., 1872, p. 187. Am. Jr. Med. Sc., July, 1873, p. 194.		Femoral.	Popliteal aneurism.	Antiseptic treatment. Slight pulsation was noticed in the aneurism on the following day, and became marked one day after. The wound suppurated acutely, and on the eighth day after the operation an attack of bleeding took place, which proved instantly fatal. On autopsy, no trace whatever could be found of the ligature. The aneurism was found to have burst, and there was a small, jagged perforation in the artery at the seat of the ligature, through which the hemorrhage had taken place. No description is given of the state of the artery, beyond this: that the two internal coats had been fairly divided by the ligature, and there was no clot in the vessel.
17	Bickersteth. Liv. and Manch. Med. and Surg. Rep., Am. Jour. Med. Sci., Oct. 1873, p. 497.	73	Gluteal.	Traumatic aneurism.	Antiseptic treatment. Patient left hospital, cured, in a month.
18	Watson. Glasgow Med. Jr., May, 1870, p. 341.		Femoral, and afterwards external iliac.	Popliteal aneurism.	Two years previously, the femoral had been tied for the same disease, with a silk ligature. The operation had been successful, and the patient had recovered perfectly, but a secondary aneurism made its appearance in the position of the first. On September 10, 1869, the femoral was tied in Hunter's canal with carbolized catgut. Silk sutures were introduced, but not tightened for some hours, in order to allow the escape of the serum. The aneurism still continued to pulsate, and on the 15th of September (five days after first operation) the external iliac was tied, antiseptically, with carbolized catgut. The skin and areolar tissue sloughed around this wound, leaving it clear and healthy. September 17, the sac, which had stopped pulsating, sloughed, both wounds granulating without suppuration. October 30, hemorrhage from sac, and limb amputated. November 15, man died. Nothing had been seen of ligatures. On autopsy, both wounds were granulating from the bottom. The arterial system was diseased. The left external iliac presented no appearance indicating that it had undergone ligation. Its lining membrane was perfect. Below the position of ligature it was somewhat reddened. <i>The vessel was entirely empty, and its calibre not diminished.</i> The calibre of the femoral, at the position where the silk ligature had been applied, two years previous, was obliterated. Where the first catgut ligature had been applied to the femoral in Hunter's canal, no traces of the ligature were found. The calibre of the vessel at that point was not diminished, but it was filled with adherent clot. The coats were deeply reddened.

Summary.—Of the eighteen cases recorded in the preceding table, twelve recovered and six died.

Healing by first intention occurred in one case only (No. 2). In one case the knot of the ligature was discharged through a sinus, which remained after the rest of the wound had healed (No. 5).

Secondary hemorrhage occurred in four cases, or 22.5 per cent.; it was readily checked in two (Nos. 3 and 4), and in two (Nos. 11 and 16) proved fatal. Premature softening of the ligature occurred in three cases (Nos. 8, 16, and 18), or in 16¼ per cent.

Cause of Death and Condition of Vessel.

In Holmes's case (No. 1), the man died from inflammation of the sac. The vessels were closed merely by thin diaphragms. In Stock's case (No. 4), the cause of death was obscure, but seems to have been septicæmia. The vessel was closed by a firm clot.

In Spence's case (No. 8), death occurred from embolism of the middle cerebral artery, caused by the premature relaxation of the ligature on the second day. The artery was not constricted.

In Watson's first case (No. 18), the man died of hemorrhage from the sac. The femoral artery was not constricted, but was filled with adherent clot, which had probably formed not long before death.

The iliac was not obstructed, and presented no traces of having been ligated. In his second case (No. 11), death occurred from hemorrhage at the point of ligation, and the artery was completely divided.

In Holden's case (No. 16), death occurred on the eighth day, from hemorrhage at the point of ligation. A small jagged perforation existed, and there was no clot. In cases of this kind it is difficult to think that the ligature is absorbed: it seems more probable that in its broken-down condition it is discharged. It might readily be overlooked.

Holmes, after mentioning Watson's and Holden's cases, says, "I have heard of another case in which a carbolized catgut ligature softened and allowed the recurrence of pulsation."* I can find no record of the case referred to.

In amputations, carbolized catgut has been frequently used by Lister† and others, but no record of their cases has been published, with the exception of two by Mr. Holmes:

1. Amputation of fore-arm. The wound healed by first

* Lancet, Sept. 13, 1872, p. 450.

† Dr. Charles T. Hunter informs me that he carefully compared the results obtained by Watson and Lister in their respective wards in the Glasgow Infirmary. The one used *no* antiseptics, and the other employed his peculiar method in every operation. There was no apparent difference in their success.

intention, excepting a small hole, which continued to discharge foul pus till death, which was caused by chronic pyæmia.

2. Amputation of thigh; death in six days. On opening the stump, the ligature which had been applied to the femoral was found softened and partly absorbed. It came away with very slight traction. Scarcely any coagulum was found in the vessel. Of this case, Holmes observes, "I am not certain that secondary hemorrhage would not have occurred, had the patient lived."*

Mr. Spence refers to a case of amputation of the thigh, of which I can discover no other record, in which hemorrhage occurred from the slipping of a carbolized catgut ligature from the femoral artery.†

CONCLUSION.

In the preceding pages the writer has endeavored to present, so far as his ability extends, a plain and unbiassed statement of our knowledge in regard to the more important materials employed for ligatures. It is hoped that sufficient information has been accumulated to enable the reader to decide for himself which of these substances is the best suited to its purpose.

Catgut prepared by soaking in water has been abandoned as a ligature. It was found to possess all the disadvantages of silk, besides some peculiar to itself. It divided the vessel, was sometimes softened prematurely, and did not generally remain encysted when healing of the wound occurred over it.

Carbolic acid, it has been maintained, has the power of greatly changing the properties of catgut. "By applying a ligature of animal tissue antiseptically upon an artery," says Lister, "we virtually surround it with a ring of living tissue, and strengthen the vessel where we obstruct it. . . . For my own part," he continues, "I should now without hesitation undertake ligature of the innominate, believing it would prove a very safe procedure."‡

The only apparent ground for Professor Lister's lively faith lies in the experiment on the calf,§ before detailed. In the writer's repetition of this experiment, one of the ligatures had disappeared, and the other (the largest) was in nearly the same condition as when applied, presenting no signs of organization. Ever since the time of Porta, it has been known that catgut could be absorbed; but that the vital fluid could enter into its substance and transform it into living tissue, though indeed "a consummation devoutly to be wished for," is highly improbable, and the writer thinks sufficiently disproved by his experiments.

Mr. Holmes adopts a more moderate tone; from his own case, he concludes—

"That arteries may be tied as securely with carbolized catgut as with silk; that such ligatures melt in the wound without being discharged from it; that an artery under such circumstances may preserve its continuity, while its tube is obliterated at the part tied; thus, that

the chief risk of secondary hemorrhage after ligation is obviated."||

The cases recorded prove that these qualities cannot be depended upon. The ligature melts away in the wound, but it may melt too rapidly, as we have seen in three out of the eighteen recorded cases. This may lead in some instances to directly fatal results, as in Spence's case, or as in Holden's and Watson's cases. The ligature may remain long enough in place to set up ulcerative action in the external coat, and yet not keep the internal coats long enough in contact to insure adhesion. Is it safe to intrust our patient's life to a ligature which may become completely softened in less than eight days?¶

Why in some cases catgut should become softened so rapidly, it is difficult to explain, just as we do not understand why it sometimes becomes encysted and is sometimes absorbed. It may be that in some cases the secretions of the wound have a greater corroding power than in others.

That the chief risk of secondary hemorrhage is avoided is, unfortunately, an assertion not warranted by experience; for, as we have seen, this was the cause of death in two instances, or one-ninth of the recorded cases. Out of the six hundred cases ligated in the ordinary manner recorded by Porta, who is noted for his accuracy, but one-twentieth died of this accident.

Carbolic acid seems to render catgut more irritating to the tissues; for, as has been seen, the majority of experiments in which carbolized catgut was inserted under the skin, or used for sutures, were attended with suppuration. This is in marked contrast with silk.

With *silver* the results of practical experience have proved so unsatisfactory in operations on arteries in their continuity that probably it will be rarely used hereafter as a ligature. Thus, three out of the eleven tabulated cases perished of secondary hemorrhage. Even in the lower animals, the writer's experiments have shown that it generally divides the vessel.

Howard's theory, that this result would not ensue if the silver were applied so as only to diminish the calibre of the vessel, is not sustained by the results of the case on which he operated. Porta's experiments with the slack silk ligature also tend to disprove it. In one (No. XVIII.) of the writer's experiments, the application of a silver ligature, after Howard's plan, was followed by the formation of a "false aneurism."

In other operations, the use of silver must be exceedingly inconvenient, as any one may test for himself by attempting to tie a vessel with it. It has no compensating advantages. This statement will be borne out by an examination of the cases given.

It seems that metallic ligatures were first suggested from the idea that balls when lodged in the tissues were generally harmless. That this idea is unfounded is proved by the observations of Hutin, chief surgeon of the Hôtel des Invalides, Paris. He examined four thousand men in five years. Two hun-

* Lancet, Nov. 1872, p. 564.

† Spence, loc. citat.

‡ Lancet, April 3, 1869, p. 455.

§ It should be remembered that at the time Lister wrote the article quoted from, carbolized catgut had never been employed on man.

|| Loc. citat.

¶ See Experiment XXIX.

dred and twelve of these had bullets, or similar substances, lodged in their bodies; out of which number only twelve suffered no inconvenience.

In the writer's experiments in which pieces of silver were inserted in the tissues, it seems that the chief cause of the suppuration which generally ensued was the inflexibility of the metal, so that it could not accommodate its shape readily to the movements of the parts.

Lead has not this disadvantage; but, as a ligature, there is no reason to believe that it would be superior to silver. It is to be wished, however, that we had more clinical experience on this point.

Silk has been accused by Simpson of delaying the union of wounds, and rendering pyæmia more frequent.

"It rapidly imbibes from the surrounding tissue," says Simpson, "animal fluids into its substance; and these dead fluids speedily decompose and render the threads morbidly poisonous and irritant agents to the contiguous living tissues."*

These assertions—for they are nothing more—have generally been denied by practical surgeons. Porta's experiments, which are confirmed by those of the writer, prove that, in the lower animals, silk is generally unirritating.

Practically, the plan of burying silk ligatures in the tissues has not been found successful, as a general rule; but it remains yet to be proved that the presence of the ligature, as now used, is injurious. In fact, some surgeons maintain that the thread acts beneficially, by draining the deeper parts of the wound.

The healing of large wounds by first intention is rare, but it sometimes occurs, in cases where silk is used. Thus, Dr. Charles T. Hunter has furnished me with the details of a case in which he excised the breast, using silk ligatures and sutures; union occurred by first intention, except at one spot, from which about half a drachm of pus was discharged, because a suture had been allowed to remain too long in place.

As has been shown, secondary hemorrhage is less common in operations on arteries in their continuity, where silk is used, than where the other materials are employed; and in other operations it is quite uncommon.

From a consideration of the preceding facts, it is believed that silk is the safest, and therefore the best, material yet discovered for the ligation of arteries.

THERAPEUTIC NOTES.

"KOUMISS."—The following formula is that of Dr. Townsend, of Cork: "R. New milk, one quart; good thick milk (sour?) or fresh buttermilk, one noggin [a noggin is one gill]; white sugar, three or four lumps. Mix thoroughly till the sugar is dissolved; keep in a warm place in a jug ten hours; pour from jug to jug till quite smooth; bottle in soda-water bottles, velvet corks, tied down; let remain in a warm place twenty-four hours in summer, thirty-six in winter. Shake well before taken.

Its fermentation is the test of excellence. Drink in quantities."—*A. Bigelow, in Boston Medical and Surgical Journal.*

TREATMENT OF ECZEMA PAPULOSUM.—M. Bazin uses the following in cases of this form of eczema accompanied by dyspepsia, etc.:

R Sodii bicarb., ʒiʒi;

Syrupi saponariæ, fʒviij.—M.

Sig.—Tablespoonful morning and evening.

Externally the following:

R Boracis, gr. xxx;

Glycerinæ, ʒiiss;

Aquæ destillat., ad fʒx.

This lotion is to be applied, rather warm, morning and evening, and the skin is afterwards to be powdered with starch. Occasionally starch-baths—two pounds of starch to the bath—are found to give relief.

NEW MODE OF ADMINISTERING RAW MEAT.—Dr. Yvon gives the following method of preparing a palatable mixture having all the virtues of fresh meat while possessing an agreeable taste:

Raw meat (fillet of beef), 250 parts,

Sweet almonds (charred), 75 "

Bitter almonds, 50 "

White sugar, 80 "

The mixture is to be rubbed slowly up in a mortar until a homogeneous paste is obtained, adding from time to time a sufficient quantity of water to give a proper consistency. The amount of water may be so varied as to give a solid or a liquid mixture. The liquid, which is in the form of an emulsion, will slowly settle, but may easily be mixed again by shaking lightly. It may be preserved unchanged for a long time if kept in a cool and dry place. In order to render it more nourishing, the yolks of one or more eggs may be added.

TREATMENT OF ANTHRAX BY SUBCUTANEOUS INCISIONS.—M. Guérin recommends this mode of treatment as preferable to that ordinarily practised, which involves the exposure to the air of the wounds made. A puncture is made through the summit of the tumor, and then the various crucial incisions are completed subcutaneously without further opening. By this method of operation the interminable suppuration often observed after operation for anthrax is avoided, as well as the not infrequent hemorrhages and also the large eschars very apt to result from the usual procedure.

After the incision is made as above, no further treatment is necessary excepting the use of poultices. Accidents from infection are rare. The incision may be made as soon as induration is established.

INTERTRIGO.—As chafing of the skin of various parts of the body is quite common at this time of the year, the following formula may prove timely:

R Bismuth. subnitrat.,

Glycerinæ, aa ʒij.—M.

A few drops of tincture of cochineal may be added to give the mixture a flesh-tint, and a little water may be added in warm weather. It may be smeared over the opposing surfaces after they have been carefully cleaned.

ICE IN BLENNORRHAGIC CYSTITIS.—In cases of blennorrhagic cystitis accompanied by painful erections, etc., small ovoid pieces of ice introduced into the rectum just within the sphincter are found to give decided relief. The ice may be renewed every hour, and two or three applications will usually suffice to give relief. Little or no curative action, of course, can be expected.

* Acupressure, p. 23.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

EDITORIAL.

THE VISION OF MALTHUS.

NOT long since, we took occasion to lay before our readers some statistics showing that the average subsistence and means of comfort for the race were increasing. This it appears is true chiefly, if not solely, in what we may call the enlightened nations,—those which are in reality or in origin European. In India, on the other hand, the vision of the much-derided seer seems to be taking the grim outlines of a reality. It appears that the population of that country is now, for the first time within the historical period, rapidly increasing. Formerly, the constant wars between the numerous native princes, the deadly arts of the Thugs, the family broils, the secret practices of the poisoners, the suttee, the car of Juggernaut, and, above all, the universal practice of infanticide, kept down the population. The English rule has, however, closed most of these outlets, and the result is daily becoming more apparent. In Bengal the traditional population was 43,000,000, but a recent census has shown that there are at present 66,000,000 of inhabitants. This seems a cheering result to the philanthropist; but there is a dark side to the picture, and there are many reasons for believing that the national infanticide, to us simply an atrocious and worse than brutal crime, was really the outgrowth of a necessity and the result of that peculiar instinct of self-preservation which often leads masses of people to acts seemingly most foolish or wicked, but, in reality, safeguards against greater evils.

Already in many parts of India the population is as dense as anywhere in the world; the habits of the people, and the very structure of society, are insuperably opposed to change of locality. What is the result? The great mass of the natives are in the depths of poverty. According to a recent writer, one-fourth of the agricultural laborers in Bengal earn only ten shillings a month apiece.

Without further discussion, it is plain that the barest subsistence can alone be commanded by these laborers for their families. This subsistence is almost solely composed of rice. The ordinary price of this grain, in India, is one and a half farthings per pound; so that a laborer can purchase of it three hundred and twenty pounds with his month's wages. Let, however, the crop fail, and rice advance to five farthings a pound, and the laborer can purchase only ninety-six pounds. The advance is less than an English penny, but it reduces the purchasing power of a man's wages to less than one-third of the normal amount. Practically, this advance in the cost of rice has been found to mean actual, present famine,—men, women, and children starving in their hovels, dying by the way-side, perishing of hunger in the fields. Our notions of famine are that food is not in the country. But, under the stimulus of a higher price abroad, in India the sustenance may be streaming out of the sea-ports, whilst the people are dying for food in country and in city.

As a result of the increase of population under Christianizing influences, famines, which were formerly infrequent, have become frightfully common. Since 1857 there have been, in India, no less than four; some of them of great severity.

The remedy for famine which the native potentate applied was simply to let things right themselves,—to allow the people to die until the demand for food was decreased to the supply. The British government recently has introduced the Christian policy of feeding the starving. This, it is readily seen, must increase the evil in the long run, although giving relief for the present. Fools, it is said, rush in where wise men fear to tread; but we may venture an opinion that the trouble must be met and conquered by other means. Grafting a portion of European civilization upon an old civilization like that of India naturally leads to the bringing forth of bad fruit. Two diverse, unlike halves can rarely be joined into a seemly whole. The true remedy for India is, we believe, to be found in the complete supplanting of the Oriental civilization by a European civilization, so modified as to suit the exigencies of climate and of race. Let a habit of emi-

gration be established, so that there shall not be in one part of the country vast uninhabited jungles, and in another overcrowded fields; let rotation of crops be introduced, and the dangers of a dependence upon a single staple be insisted upon; let, in brief, a revolution of the Hindoo habits occur, and though during the transition-period enormous suffering must be endured, yet in the end, we believe, a complete new life and a reorganized society will be safely achieved,—a result without which Christianity will probably in India prove a failure.

CORRESPONDENCE.

BOSTON, MASS., June 4, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SINCE I left my native city I have roved considerably, and have had opportunity to become somewhat familiar with various localities. At present I am sojourning in Boston, and thus far have had sufficient "nerve and muscle to contend with New England climate and customs." The climate, to be sure, during the past three months, has been trying enough to one's constitution: in fact, we have had many just such disagreeable days as are not unfrequently encountered in your city in the spring. So far as the customs are concerned, if by this term one may include the treatment he is likely to meet with from the natives of this land of the Puritans, especially the doctors, I can truly say that nowhere could a stranger have been more kindly received than I have been. It may be true that the community here is conservative in its tendencies, and will not at first sight be "gushing" towards a new-comer, or admit him to full standing, but demands that he shall in some way show himself worthy of advancement. However, when once this demand has been complied with, I can affirm that, so far as our profession is concerned, every encouragement is offered by the older members to the younger.

The Massachusetts Medical Society, which began its yearly meeting June 2 in its usually quiet and unobtrusive manner, is not only the oldest, but also by far the largest, of the State Societies of our country, having been incorporated in 1781, and numbering at the present time some thirteen hundred members. It invites to, and seeks to include in, its membership, all properly qualified practitioners of legitimate medicine throughout the State; and any physician who is not a member is, with propriety, suspected as to the soundness of his professional character.

During the forenoon the members availed themselves of the opportunity to visit the two principal hospitals of Boston, and also the Brighton Abattoir, which is, says the last number of the *Boston Medical and Surgical Journal*, "perhaps the greatest triumph of the State Board of Health." It has, of late, become a popular

resort for consumptives, who are trying the benefit of drinking blood fresh from the slaughtered animals. As to its efficacy, a physician, several of whose patients have regularly indulged in this agreeable pastime, is reported to have said that as yet they had failed to derive any advantage therefrom.

At the Massachusetts General Hospital there was a surgical visit, with operations. Opportunity was also given to inspect the two new wards, the Warren and Jackson, which have been recently opened. They are thus described in the last report of the hospital: "These structures are modelled somewhat upon the plan of army field-hospitals, with such modifications as climate and greater permanency require. The dimensions are forty-five by fifty-five feet, by fifteen and a half feet high to the eaves. Frames and outside walls of iron; high-pitched trussed roofs, at apex of which are ventilators, ten feet square, with chimney-stacks in centre. They are connected with the main hospital by corridors. Warren ward is one story high, without interior divisions, forty-four feet square inside, sixteen feet high at walls, and twenty-two and a half feet high in centre; arranged for twenty beds, allowing about one thousand eight hundred and forty cubic feet of space to each bed." Windows are arranged upon three sides, and so open as to allow a circulation of air without a direct draught upon the beds. For heating-purposes, a chimney-stack is placed in the centre of the ward, on two opposite faces of which are open fireplaces, and on the other two open Franklin soapstone stoves. Steam radiators, hung beneath the floor, and supplied with fresh air from without, also assist in heating. "A glazed door opens upon a platform in the south front, over which is to be an awning in hot weather. Jackson ward is similar in construction and dimensions, excepting that the interior is divided into eight rooms, each twelve by eighteen feet, fifteen and a half feet high, containing three thousand cubic feet of space, and of sufficient size for two beds each. Each room has an open Franklin soapstone stove. The ward is divided by a centre and a cross corridor, twenty-one and a half feet high, which, as well as the rooms, are connected with the large ventilator in the roof."

At the City Hospital there was also a surgical visit, with operations. Of great interest was the exhibition of patients in the two tents that were spread in the yard. Several cases which, while confined in the walls of the Hospital, were *in extremis*, are fairly on the road to recovery since they began to camp out.

At 12 M. the Society met in the hall of the Lowell Institute, to listen to the reading of papers.

The first paper was by Dr. J. O. Whitney, of Pawtucket, who reported a case of dilated kidney in a patient 24 years of age. When three years old he had dysentery, and since then he has been subject to attacks of pain in the left lumbar region and in the neighboring part of the abdomen. When seen first by Dr. W., there was a tumor occupying the left side of the abdomen, and extending towards the right, beyond the median line. The patient was then in a very weak condition.

The diagnosis, arrived at with a good deal of difficulty, was hydronephrosis. The tumor was evacuated with the aspirator, and, after a few days, a second time; the fluid obtained at theappings confirming the diagnosis. The patient is now well. The paper concluded with an account of the literature of the subject, and a discussion as to the difficulty of diagnosis and the treatment of cases of hydronephrosis.

To a listener, it seemed that the reader intimated quite often enough the superiority of his diagnostic powers over those of other gentlemen whom he called in consultation, and that he spoke with quite as much authority as an experience of one case would allow.

Dr. Douglass Graham read a paper on Massage. He stated that the ancients sometimes employed it in the treatment of disease. He discussed particularly its advantages in subacute rheumatism and in recent sprains.

The third paper was by Dr. T. B. Curtis, of Boston, on Cotton-Wool Dressings. This method, as adopted by Guérin, of Paris, was detailed in a very interesting way by the reader, who had personal experience in its employment in Guérin's ward. It is one of the forms of the antiseptic method of dressing wounds, the theory being that the septic germs which the air contains are filtered out on their passage through the cotton, so that only pure air reaches the wound. This mode is of especial use in the dressing of stumps after amputations. The cotton needs to be applied in great abundance; Guérin's rule being, for those who were applying it for the first time, to put on *too much*. It is to be firmly bandaged to the wound, and not to be removed, if all goes well, for three weeks. After that time, the wound is to be dressed in the ordinary way. It is judged that the wound is doing well, first, if the condition of the patient, secondly, if the dressing, remain satisfactory. The first of these two points is in a great measure determined by careful observations with the thermometer, which will rise abnormally should unfavorable complications arise, while if little or no discharge appears from under the cotton the second point is satisfactorily established.

Dr. Curtis did not claim that pyæmia and septicæmia were entirely unknown in cases where this dressing had been employed, but that their frequency seemed to be much diminished since Guérin had adopted his method. The application gives great comfort to the patient, the reparative process being accompanied with scarcely any pain. The dressing in time becomes by no means odorless.

Dr. E. P. Hurd, of Newburyport, then discussed at length the Germ-Theory of Disease. He gave a *résumé* of the views of Hallier, Cohn, Pasteur, Salisbury, Beale, and others, but considered that they were all of them speculations, and none of them established facts. As to the origin of disease, or in what it consists, we must as yet confess our ignorance.

Chronic Cervical Endometritis formed the subject of a paper by Dr. S. D. Presbrey, of Taunton. We failed to discover anything new in the communication, unless

it was the suggestion that, by means of an instrument for insufflation, powders, as of tannin or persulphate of iron, could be applied to the interior of the uterus with facility.

Dr. F. W. Goss, of Roxbury, next called attention to the dressing of wounds. The various methods now in vogue in the dressing of wounds were considered, of which the occlusive treatment and the open treatment are the extremes. The reader believed that, in view of these conflicting methods, it was well to keep in mind the leading principles held by the best practitioners from time immemorial in the treatment of wounds. We heard it remarked that the article was a temperate one, and might be very useful.

The last paper of the afternoon was by Dr. J. Baxter Upham, of Boston, entitled "Reflections on the late Epidemic of Cerebro-Spinal Meningitis in Massachusetts." The statistics of the epidemic had evidently been collected with much care and labor, and their results were concisely stated. Dr. Upham remarked that it was surprising how varied had been the treatment, and yet how confident different practitioners had been in modes as distinct as possible. No conclusion could be gathered from the returns as to what therapeutic agents could be most advantageously employed in cerebro-spinal meningitis.

During the evening of Tuesday the Councillors elected the following officers for the ensuing year: *President*, Dr. B. E. Colting, of Roxbury; *Vice-President*, Dr. Joseph Sargent, of Worcester; *Treasurer*, Dr. Francis Minot, of Boston; *Corresponding Secretary*, Dr. C. W. Swan; *Recording Secretary*, Dr. F. W. Draper; *Librarian*, Dr. D. H. Hayden, all of Boston. Dr. G. H. Lyman, of Boston, was appointed Orator, and Dr. T. N. Stone, of Wellfleet, the Anniversary Chairman for the next annual meeting.

Wednesday the Society reassembled at 10 A.M., the President, Dr. George C. Shattuck, of Boston, in the chair.

It was announced that Professor Henry W. Acland, of Oxford, England, had been elected an honorary member.

Dr. Edward Cowles, the Superintendent of Boston City Hospital, read a paper on the Treatment of the Sick in Tents and Temporary Hospitals. The reader held that recent observation and experience had shown that more favorable results were obtained from the treatment of patients in temporary structures than when they were placed in regular hospitals. He contended that it was a mistake to spend vast sums of money to erect costly and magnificent buildings, when a much less amount could, with far greater advantage to the patients, build a hospital with a view to its removal in a few years. He showed a diagram, and gave an account of the structure of the tents in use at the institution with which he is connected.

In the discussion which followed, several members coincided with Dr. Cowles in the views he had advanced, and related their experience in the late rebellion in confirmation.

Dr. Henry Clarke, of Worcester, then read a paper on the Surgical Treatment of Empyema. He stated that the plan which was now recognized as the best mode of treatment in such cases—that of a free opening into the chest, to remain unclosed as long as pus continued to be secreted—was recommended by Hippocrates. The paper was a tiresome one, from the details of cases which it contained. What a want of good judgment it shows to attempt to read the daily record of cases in all its items! It may do for the printer, but is wearisome to any audience.

Transfusion was the subject treated of by Dr. J. R. Chadwick, of Boston. His paper was concise, interesting, and to the point. After stating the history of the procedure, its physiological and other relations, and the class of cases to which it was adapted, Dr. C. showed Aveling's apparatus for the performance of immediate transfusion, and explained its method of use.

At one o'clock, P.M., the Annual Address was delivered by Dr. Nathan Allen, of Lowell, on The Medical Problems of the Day. The part of greatest interest was in regard to the law of human increase. Dr. Allen holds it to be an established fact that our native population is relatively decreasing,—the births hardly equaling the deaths,—while the children of foreigners are rapidly supplying their places; so that if the present state of things continues the descendants of the old English stock will soon be in the minority.

The hour allotted for the discourse was evidently too short a time for the speaker to present in full all he had prepared: nevertheless, the selections were made with judgment, and were so connected as to give the audience a good understanding of the orator's views.

At two o'clock, the Fellows, to the number of nearly eight hundred, passed into the Music Hall to the Anniversary; and after the dinner, the Anniversary Chairman, Dr. R. L. Hodgdon, of Arlington, called the meeting to order and gave an address of welcome.

To the toast, "The Massachusetts Medical Society," the retiring President, Dr. George C. Shattuck, responded. He alluded to the changes that had taken place in the course of study at the Harvard Medical School, insuring a better education to its students than under the old system, and that its graduates would enter upon their professional work with a better preparation, therefore, than had been possible before. Reference was also made to the trial and expulsion of the homœopathic members, as a vindication by the Society of the principles and purposes for which it exists. As to the admission of female practitioners, they had themselves settled the question by putting their school into the hands of the homœopaths.

Toasts were given and speeches were made by the Chaplain of the day, Rev. Mr. King, of Roxbury, by Dr. Allen, by Dr. Colting, the President elect, by Dr. Parker, formerly of China, Dr. Green, of Boston, etc., etc. Dr. Stone, of Wellfleet, read an original and humorous poem.

Thus ended a very pleasant session of this venerable

Society,—one of the pleasantest and most profitable ever held, I am told. PENN.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held March 11, 1874, at 8 o'clock P.M.

The PRESIDENT, DR. W. L. ATLEE, in the chair.

Dr. B. LEE had recently seen several cases which were of interest as presenting considerable obscurity in regard to diagnosis. The first which he would mention was that of a little girl about six years of age, residing in the upper part of the city, who was placed under his care by Prof. Stillé, with the information that the case had been treated by a female physician as one of disease of the right hip-joint. Not being satisfied with her management of the case, however, the parents had requested him to examine the child. Prof. S. had been unable to discover the signs of hip-disease, but thought that he had detected a spinal curvature in the lumbar region, and considered that this was probably the cause of her lameness. He had gone to the case with the preconceived notion that he simply had to differentiate between disease of the hip and Pott's disease. The history was as follows. The parents were both in good health, and had older children whose health was also good. This child had never been robust, nor had she ever had any very serious illness. Last summer, however, she had an attack of fever, intermittent and remittent, the mother was not certain which, lasting about ten days. Some time after this it was observed that she limped in walking, and became easily tired. She was taken to the sea-shore, but did not react well after surf-bathing, and appeared to walk worse rather than better. Her condition had not changed materially up to the time that he saw her, except that she was inclined to hold the knee bent, could endure less fatigue, and evinced more nervous excitability. The points which he made out on comparison of the two limbs were as follows. The right limb was half an inch shorter than the left. The flexors of the right knee were slightly contracted. The nates of the right side were smaller than those of the left, but did not present the characteristic flattening of hip-disease. It was impossible to determine whether upward force produced pain, as the child cried incessantly during the entire examination. The right limb could be abducted and rotated with ease, but the left presented considerable resistance to any effort to move it in these directions. The child had not been subject to "starting-pains" at night. The only pain complained of was behind the right thigh above the knee. Both in standing and walking, the foot was set flat upon the floor, and in a natural position. The signs of the early stage of coxalgia, therefore,—viz., apparent lengthening, fixation of the hip-joint with contraction of the adductors, eversion of the toes, elevation of the heel, and spasmodic contractions during sleep, with pain in the knee and along the front of the limb,—were every one absent as regarded the right limb. Certain of them were present in the left, but that had never been complained of. So far, results were negative. There was no hip-disease. Now for the spine. On placing the child in the erect standing posture, there certainly was a curve, having its convexity to the right, in the lumbar region, but it could be removed by direct pressure and by the muscular efforts of the patient. She could stoop forward, flexing the spine, to pick an object up from the floor.

She complained of no ventral pain, or of morning rigidity; her toes were not inverted; the curve presented no angularity whatever; and on placing her on her knees, or laying her on her face, it was obliterated. He was therefore compelled to decide against the existence of any organic affection of the spine. The curve was simply the result of the shortening of the right limb, and had no pathological significance. The child was by this time in such an excited condition that he considered it unwise to proceed further with the examination, and, confessing his inability to arrive at a definite conclusion, he proposed to continue the investigation another day. Three days later he saw the child again, and this time added the following facts to those which he had before determined. The temperature of the right limb was decidedly lower than that of the left. Its circumference in muscular regions was from half an inch to an inch less. The muscles were soft and flabby, and, although all the motions of the limb were accurately made, they were less vigorous than those of its fellow. The ligaments of the hip-joint were somewhat relaxed. In other words, the innervation of the limb, as regarded circulation, calorification, nutrition, and muscular force, was decidedly deficient. Coupling this fact with the history, he thought that he had found ground to stand upon. The attack of fever which she had experienced eight months before was simply symptomatic of an attack of inflammation of the meninges of the spinal cord, of moderate severity, possibly malarial in its origin, which would account for the suspicion of intermittent. This was followed by effusion, producing loss of power in the right limb, evidenced by the difficulty of locomotion, and gradually by atrophy and by contraction of the hamstring tendons; the other limb being either not affected at all, or, as is often the case in the atrophic paralysis of childhood, speedily recovering. Dr. Grier, who applied the galvanic tests at Dr. Lee's request, found in the response which the muscles of the two limbs gave, an entire confirmation of the diagnosis.

The lecturer of the evening having now arrived, Dr. Lee declined to occupy longer the time of the Society. Dr. L. J. Deal then read a paper on "The Relation of the County Society to the Physician, and the Physician to the County Society."

[Although this paper was most excellent and very well received, yet, owing to the matter not being of general scientific interest, we have been forced by the very crowded state of our columns to omit both it and the discussion to which it gave rise.—ED. P. M. T.]

Dr. KEYSER mentioned the case of a child seven months old, which was brought to him the previous day with evidences of an old iritis and occlusion of the pupils of both eyes, without ever having had any inflammation in either eye since its birth. The child is fat and healthy; was born in perfect condition, as certified to by both mother and nurse, who brought the child to his office. The left eye was small and undeveloped, the iris drawn strongly and closely to the outer edge under the sclero-corneal line, pupil completely obliterated. The right eye was full size, cornea clear, complete circular (synechia) adhesion of the iris to the anterior capsule, and pupil filled in with lymph so as to be entirely occluded.

The right nostril was almost closed by a diaphragm of tissue across it, through which a very small round opening could be seen. This hole was just large enough to allow a No. 1 Bowman's tube to pass through. The left nostril was natural and free. There was considerable discharge of mucus and blood at times from the left nostril. Rather doubting the history of no inflammation of the eyes after birth, Dr. K. wrote to the family physician, Dr. Stine, for information, who replied "that the child was born August 19 last,

full-grown and perfectly healthy; had no sore eyes nor any inflammation of the eyes; the infant continuing in good health up to the 25th of the following month, when he was called to visit it for a severe attack of catarrh in the nose,—nose and ears discharging freely, but had no inflammation in either eye." Under all these circumstances, then, there must have been inflammation before birth—an "iritis in utero."

Constitutional syphilis is suspected, but could not be learned from the parties. The case is very rare and interesting.

GLEANINGS FROM OUR EXCHANGES.

MERCURY AS A CHOLAGOGUE (*The Lancet*, May 2, 1874).—In a lecture on Functional Derangements of the Liver, Dr. Murchison expressed his belief that mercury and allied purgatives produce bilious stools by irritating the upper part of the bowel and sweeping on the bile before there is time for its reabsorption. He also added, however, that there are grounds for believing that, apart from its increasing the discharge of bile from the bowel, mercury exerts a beneficial action in many functional derangements of the liver, in whatever way this is to be explained. Patients of the greatest intelligence suffering from hepatic disorders constantly declare that they derive benefit from occasional or repeated doses of mercurials which no other medicine or treatment of any sort confers. It is not impossible that the good effects of mercury on the liver, and in some forms of inflammation, may be due to its property of promoting disintegration. Mercury appears to have the power of rendering effused fibrin less cohesive, and so more easily removed by absorption than it otherwise would be. Modern physicians of high standing, and little likely to be accused of credulity as to the beneficial action of drugs, have thought that mercury is useful in croup, by causing a degradation and disintegration of the plastic membrane. If this be so, it seems not improbable that mercury, which from experiments we know to reach the liver, may, under certain circumstances, act beneficially by promoting, or in some way influencing, the disintegration of albumen. The remarkable effect of mercury on constitutional syphilis probably admits of a similar explanation. In whatever way it is to be explained, he considers the clinical proofs of the efficacy of mercury in certain derangements of the liver as overwhelming, and remarks that he says so the more advisedly because he was taught to regard mercury as a remedy worse than useless, not only in hepatic diseases, but also in syphilis; his present convictions having been forced upon him by experience.

EPILEPSY AND MIGRAINE (*The Journal of Mental Science*, April, 1874).—It having been asserted that the paroxysms of some forms of sick-headache resemble epileptic attacks, and may even develop into true specimens of the latter, and bromide of potassium having been found to have a decided beneficial effect in such condition, Mr. Richard Green has employed Indian hemp in nine cases of epilepsy, arguing that if there were any real identity between the diseases it might be expected to do good, as it unquestionably does in paroxysms of migraine. In no case, however, was there any diminution in the number of seizures; and in seven out of the nine there was a slight increase.

PARALYSIS OF THE HAND AND FORE-ARM CAUSED BY ESMARCH'S BLOODLESS METHOD (*The Medical Record*, May 15, 1874).—Dr. Robert Weir reports the case of a young man in whom it was found necessary to remove some dead bone from the elbow-joint. Esmarch's bandage was applied, the rubber cord of the diameter

of one-quarter of an inch being, as usual, tightly drawn three times around the limb at the junction of the upper and the middle third of the arm. The compression was continued about three-quarters of an hour. After the inflammatory reaction of the wound had passed away, it was found that the patient was unable to flex or extend any of the fingers, or the hand on the fore-arm. He complained of numbness on the tips of all his fingers, of the palm, and anterior surface of the fore-arm. The lesion was mainly confined to the median nerve. This condition remained unchanged for some time, but he afterwards rapidly regained the use of the affected muscles under the application of the galvanic current.

WOUND OF THE BRAIN—RECOVERY (*The Richmond and Louisville Medical Journal*, May, 1874).—Dr. R. F. Baldwin reports the case of a lad sixteen years old who was accidentally wounded by the discharge of a Colt's pocket-pistol in the hands of a companion a few feet distant. Upon receipt of the shot the boy fell with violence, but did not lose consciousness. The ball, about the size of a buckshot, entered the right frontal bone an inch above the centre of the eyebrow, and, passing through the brain, lodged in the occipital bone near the centres of the occipital cross. A silver probe passed by its own weight to the centre of the brain without touching the ball. As a precautionary measure he was bled, and Epsom salts were administered. The wound healed rapidly without any constitutional disturbance, and in ten days he returned to his home. He is still living in good health, and has never suffered the slightest inconvenience from the accident.

PHOSPHORUS IN MELANCHOLIA (*The Journal of Mental Science*, April, 1874).—Dr. S. W. D. Williams reports six cases of melancholia treated with phosphorus, three of which resulted in recovery, two in partial benefit, and one in entire failure. In the latter case a cure was rapidly effected, after the withdrawal of the phosphorus, by means of opium. In each case the dose was one pill of one-thirtieth of a grain twice daily, increasing to three or four pills daily. No toxic effects were observed, except a slight warmth in the epigastrium.

ATROPIA-POISONING.—Dr. T. H. Newland reports (*St. Louis Surgical and Medical Journal* for June) a case of atropia-poisoning in an adult. One and a quarter grains ingested; vomiting about an hour after ingestion; one-fourth of a grain of morphia every twenty, and two grains of carbonate of ammonium every ten minutes for two hours; recovery.

MISCELLANY.

SOME years ago we read an article upon an animal called the "devil," a native, we believe, of Van Diemen's Land, in which the writer, after giving instances of the creature's extraordinary ferocity, ended, "Of all animals, the very devil of devils is the devil itself." English colonies would seem also to own a monopoly of the same type as seen in quacks. Recently, in British Guiana, according to the *British Medical Journal*, a midwife named Amsterdam was called to see an unfortunate woman then in labor. Without giving much space to the details of the treatment instituted by this daughter of Belial, we quote the following specimen:

"The 'stretching' with the rope, which we have already spoken of, is described by a witness: Three women tied the deceased's wrists with tarred rope, twisting her up to the beam of the room with her legs

dangling. . . . One beat her with a strap with a buckle to the end. They repeated this every now and then, the deceased begging them to let her down, as she was so weak. She was lying from Friday to Monday on the bare boards. There ought to have been no difficulty in the birth, but the woman died undelivered, after nearly three days of agony."

THE NECROMETER.—It is stated that M. Bouchut has obtained the prize offered by the French Academy for an easy method of distinguishing simulated from real death. His "necrometer" appears to be simply a peculiar thermometer so adapted as to fit the axilla and to mark zero when death has occurred.

NOTES AND QUERIES.

As we admitted to our columns a letter sharply commenting upon the brain-experiment of Prof. Bartholow, it is but fair that we give place to the following letter, originally published in the *British Medical Journal*:

"SIR,—A case of epithelioma exposing the brain, on which I ventured to make some experiments, has excited unfavorable comment in your widely circulated journal and elsewhere. Under these circumstances, I beg to offer some explanations, which, whilst they do not justify the experiments in question, at least, it appears to me, put the matter in a less offensive shape.

"1. The patient was hopelessly diseased with a rodent ulcer, which had already invaded the dura mater. The ulcer was rapidly extending, and threatened an early extinction of life.

"2. The patient consented to have the experiments made.

"3. It was believed that fine insulated needles could be introduced without injury that would affect the progress and termination of the case, for the following reasons: The brain has been incised to permit the escape of pus, a notable and successful example of which has recently occurred in London. Portions of the brain-substance have been lost, and yet the patient survived; for example, the Massachusetts case, in which a tamping-iron was driven through the brain, the patient recovering, and dying many years afterwards of another malady.

"4. The faradic current was used; and this has, as is well known, no electrolytic action.

"5. The fatal result was attributable to the progress of the epithelioma. The erosion of the skull already had existed thirteen months. The thrombus found *post mortem* in the longitudinal sinus could not have been caused by the needles, which were introduced some distance from it on each side.

"Notwithstanding my sanguine expectations, based on the facts above stated, that small insulated needle electrodes could be introduced without injury into the cerebral substance, I now know that I was mistaken. To repeat such experiments with the knowledge we now have that injury will be done by them—although they did not cause the fatal result in my own case—would be in the highest degree criminal. I can only now express my regret that facts which I hoped would further, in some slight degree, the progress of knowledge, were obtained at the expense of some injury to the patient.

"I am, etc.,
"ROBERTS BARTHOLOW."

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 9 TO JUNE 15, 1874, INCLUSIVE.

HASSON, A. B., SURGEON.—Granted leave of absence for fourteen days, to commence on 13th inst. S. O. 113, Military Division of the Atlantic, June 9, 1874.

WRIGHT, J. P., SURGEON.—Granted leave of absence for thirty days. S. O. 129, A. G. O., June 11, 1874.

LAUDERDALE, J. V., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Adams, R. I. S. O. 116, Military Division of the Atlantic, June 12, 1874.

GHISELIN, JAMES T., SURGEON.—Resigned June 6, 1874.

SATURDAY, JUNE 27, 1874.

ORIGINAL COMMUNICATIONS.

ON TINNITUS AURIUM.

BY LAURENCE TURNBULL, M.D.,

Aural Surgeon, Howard Hospital, Philadelphia.

THE ringing noises heard in the ears are not only a symptom of the diseased condition of the organ, but also a very troublesome form of disease in itself, for after all apparent disorder has passed, the patient is still distressed and disturbed by a most persistent form of tinnitus.

Each individual, although suffering from the same symptom, generally describes it according as it is suggested by his or her habits or occupation. The old lady, fond of her cup of tea, compares the noises to the singing of the boiling kettle; while the servant in the kitchen has a constant ringing of bells in her ears. The engineer will tell you that the noise is like a faint locomotive-whistle; the miller compares it to the whirr of the wheel; while the boiler-maker has a succession of knockings in his ears; the gardener or farmer talks of it as a rustling of leaves, or waving of ripe grain; the sailor, or dweller near the sea, identifies it with the roar of the ocean.

Then we have the agreeable forms, as in an old deaf lady, who informed the writer that she was often serenaded by lovely voices, and would inquire of her children if they did not hear the same sweet sounds. Another pleasant form noticed by a recent writer* was in the case of a middle-aged woman, who spoke of the noise as a low singing of birds.

There are some forms which in time, if neglected, become almost a mental malady if the brain is diseased, or if there is a hereditary tendency in the family, but we have never known of a case of suicide from this cause, and our opinion is confirmed by Dr. Kirkbride, who for so many years has been the physician-in-chief of the Pennsylvania Hospital for the Insane in Philadelphia, expressed in a letter to the writer: "I do not now recall a case of insanity really owing to aural disease, although I think that defective hearing often aggravates some of the delusions of the insane, and disorder of the hearing-apparatus is not infrequent in insanity."

Dr. J. H. Worthington, physician-in-chief of the Friends' Asylum for the Insane (Twenty-third Ward, Philadelphia), thus writes: "I never knew a case of mental disorder which owed its existence to such disease (aural), nor any case of suicide in consequence of tinnitus aurium."

A similar opinion is expressed by Dr. John Curwen, chief physician of the Pennsylvania State Lunatic Hospital, Harrisburg, who had also a long experience as first assistant-physician of the Pennsylvania Hospital for the Insane, at Philadelphia. He writes, "I do not recollect any cases of insanity

under my care which were produced by ear-noises: all the cases of hallucination of hearing have arisen from diseases of the brain, induced in various ways. The three most decided cases now in my care are caused by intemperance and overwork, both mental and bodily, bringing on great cerebral disorder."

Von Trölsch,† in his work on the ear, says in regard to the tinnitus aurium of the insane, "It is a very important question whether the aural hallucinations occurring in insane patients do not frequently depend on peripheric tinnitus, which is exaggerated by the patients." It would be well worth the trouble of physicians for the insane to examine the ears of such patients. He further states, "I am indebted to my esteemed friend Prof. L. Meyer, formerly director of the Insane Asylum of Hamburg, for the history of a melancholic patient who was relieved of a sound in the ear (seeming to the patient to be the cry of a child) by the removal of a plug of inspissated cerumen, which caused deafness of one side. The patient, from that time forward, made a rapid and complete recovery."

Schwartz, an aural surgeon, and Köppe, a physician for the insane, have made this question a subject of investigation.

Schwartz says, "Subjective aural sensations, which are caused by demonstrable affections of the ear, may, in predisposed persons, especially when there is hereditary tendency to mental disease, become the direct cause of aural hallucinations, that may accelerate the outbreak of mental disease."‡ He states that he treated such a patient for a long time, and she was protected from a threatened attack by the local treatment of the aural disease.

Dr. Köppe, before referred to, assistant-physician to the Provincial Insane Asylum at Halle, examined this patient with Dr. Schwartz, and was convinced that the treatment caused the above-mentioned results. In other cases, insane persons who suffer from aural disease distinguish its tinnitus from their illusions or hallucinations. They hear their "sounds" simultaneously, but independently, of the tinnitus aurium.

Dr. Köppe examined thirty-one insane persons in whom considerable disease of the auditory apparatus could be detected. In none of them was there tinnitus without at the same time the existence of aural illusions and hallucinations.

Seven insane persons also had chronic hyperæmia of the vessels of the handle of the malleus, and, besides the subjective aural sensations, aural illusions and hallucinations. In two cases of inspissated cerumen, the tinnitus disappeared after the removal of the plugs of wax, but the *hallucinations remained*. In several cases, which are fully detailed, both the tinnitus and the hallucinations disappeared after local treatment of the ear. Two cases were particularly interesting, where only one ear was affected, and where the sounds were only heard on that side.‡

* Dr. Dalby, of London.

Trölsch* again states, "Perhaps we may designate the one variety as nervous tinnitus aurium, the other as material or acoustic, and which may exist at the same time."

William Harvey, F.R.C.S.,† mentions hysterical, hypochondriacal, and nervous patients, as suffering from every possible form of tinnitus. Wilde‡ says, "In some forms of hysteria, and in cases of mental aberration and lunacy, as those familiar with such know full well, the patients often complain of all manner of noises, whisperings, and unnatural sounds, but these are, I believe, generally the result of a disordered imagination, like the ocular spectra which afflict certain individuals."

Saissy,§ in treating of symptomatic tinnitus, says it depends on "nervous diseases, such as hysteria, hypochondriasis, convulsions, and mental alienations."

Dr. O. D. Pomeroy,|| of New York, made an examination of sixty lunatics at the Blackwell's Island Lunatic Asylum, New York, thirty of whom had hallucinations of hearing, and thirty had none, with the view of determining whether diseases of the ear had any agency in the production of the symptoms, and his conclusions were as follows: "The result of the examination is a little in favor of the hallucination cases being oftener associated with ear-disease. The proportion is not, however, anything like that previously quoted from Von Trölsch and others." "Neither was it possible to observe any connection between the tinnitus aurium and the hallucinations." Certainly, the aural disease did not, in a single instance, develop or excite the insanity, as has been quoted. This confirms our own examinations and correspondence, and gives a more hopeful and proper view of even the worst form of this affection. Our rule should be that if there is any hereditary tendency to mental disease, and there are persistent hallucinations resembling any of the forms we have given as examples, care should be taken that the ears be examined, and, if it be possible, this symptom removed. We cannot pass from this part of our subject without a short reference to the observations made by Nussbaumer, in which he attacks the physiological axiom that each organ of sense is capable of peculiar perceptions, which can be excited by no one of the other organs of sense. "The author himself, and his older brother, both have this peculiarity, that every perception of sound, either musical or otherwise, excites also a perception of light. His ear is so delicate that with the deep notes of a piano he is able to hear eleven over-tones, and with each one of these has a distinct perception of light. As children, he and his brother were in the habit of designating frequently the tones of different objects when struck, not by the sound, but by the color produced."

"To learn whether the perceptions of the two brothers were always the same, a long series of questions, to be answered by each, was written,

from which it seemed that, although each had a perception of light with each sound tried, yet the color of the light varied: being, for instance, for the note A, in one, dark Prussian blue, and, in the other, dark yellow.

"The color was never seen externally, but, as he expressed it, his brain suffered from the action of a sound-wave in the meatus, not only the normal but also such a change as produced in his consciousness an impression of color. When in concentrated thought, however, the perception of color might escape notice.

"In the discussion which followed, Prof. Benedict considered that the phenomena were not physiological, but pathological. Optical perceptions, as the direct result of acoustical perceptions, could only be pathological. Similar obscure diseases of the mind and brain were frequently observed in hysterical, hypochondriacal, and melancholy persons, but were not understood, as most physicians were unskilled in psychology. He predicted that similar observations to those of Nussbaumer would soon be reported, now that attention had been called to them. Finally, Prof. Benedict warned the patient against further observations on himself, lest the phenomena would overpower him, especially as it was evident that there was a hereditary tendency; possibly, heterotopia was the cause of the phenomenon."¶

THE DIAGNOSIS AND CAUSES OF TINNITUS AURIUM.

The first and most frequent cause we shall notice is the pressing of a portion of altered cerumen upon the membrana tympani. This usually arises from cold, heat, or moisture, or the three combined, detaching it from the side of the auditory canal and causing it to press on the membrane. The second cause is an elongation of the hairs in the external orifice of the auditory canal, passing across and interlacing with cerumen or epithelium scales, and producing a sound like an Æolian harp. In another form, a single hair was found to rest upon the surface of the membrana tympani. A particle of pus on the same membrane gave not only a sound, but a disagreeable one, until removed.

A third cause is a small quantity of adhesive mucus on the inner surface of the membrana tympani, or middle ear, pharyngeal orifice of the Eustachian tube, or on the mucous membrane near the tube. These conditions are almost always attendant in acute, subacute, or chronic catarrh.

A fourth cause is a foreign body in the Eustachian tube, as, for instance, a beard of barley,** or a bullet.†† In the first case, the beard caused otitis media purulenta, with most distressing noises, and was ultimately discharged through a perforation of the membrana tympani without the loss of the hearing, and with entire relief to the tinnitus. The bullet could not be removed. In a case related by Fleischmann, the result was not so satisfactory.

** Turnbull on Diseases of the Ear, p. 78.

†† Ibid., p. 94.

A man complained for years of a continuous sounding in his ears and of a very peculiar sensation in his pharynx. He died, and on a post-mortem section a beard of barley was found projecting from the pharyngeal orifice of the tube, and reaching into its osseous portion.*

A fifth cause of tinnitus occurs synchronously with the action of the heart, and may be *anæmia* or a diseased condition of the blood, or enlargement or narrowing of some of the numerous arteries or their branches in the vicinity of the ear. This narrowing occurs generally in a branch of the temporal, posterior auricular, or carotid arteries, and we can determine by pressure whether it depends upon them, after finding no physical cause in the ear itself.

A sixth class comprises a large number of doubtful cases, under the head of *nervous tinnitus*, in which it is conjectured that there is inflammation, irritation, extravasation, or disturbed circulation of blood in the labyrinth, cochlea, semicircular canal, auditory nerve, or reflected lesions of the brain.

The diagnosis in this class of cases is made by excluding all causes which would be at all possible to produce the sound in the external or middle ear.

The seventh cause is immoderate contraction of the tensor tympani muscle, which contraction not only moves the malleus and with it the membrana tympani, but also, if the contraction is excessive, the whole chain of ossicles is drawn inwards, and, as a consequence, the plate of the stirrup is pressed deeply into the oval window (fenestra ovalis), causing violent subjective noises from the intra-labyrinthal pressure. "Dr. Gruber† observes that the tensor tympani muscle arises from the cartilaginous portion of the Eustachian tube, but is connected with the tensor veli palati muscle by a tendinous prolongation in such a way that the intimate connection between the two is completed; and L. Mayer even asserts that he considers the two muscles as a single digastric muscle. It is well known how often this muscle suffers in the frequent diseases of the naso-pharyngeal structures. If we notice the soft palate and usually hypertrophied tonsils into which this muscle enters, we will see how the same is displaced and drawn out of its position, and it will be clear that this muscle in such cases is unable to properly perform its function—viz., the opening of the Eustachian tube; and this abnormality, sooner or later, will be sure to affect its companion muscle—the tensor tympani—and so cause the spasmodic contraction of the latter, which will exert a further influence upon the labyrinth."

Now the question arises, Are there any positive symptoms by which we can with certainty diagnose in the living such a retraction of the tensor tympani muscle? We must answer most decidedly in the affirmative.

I will not speak of the anamnesia, and of the subjective symptoms, which certainly deserve some consideration, but pass at once to those positive signs especially apparent in such cases. In conse-

quence of the peculiar connection between the malleus and the membrana tympani, that is, the lower end of the malleus with the adjacent portion of the membrana, it is directed inwards, while at the upper end the short process pushes it outwards; and there originate two folds, the posterior of which is much more distinct, running backward, while the anterior fold runs forward, and in the comparison of this bulging with the sunken condition of the membrane we have an important indication, which Dr. Gruber was the first to describe and employ in diagnosis.

When the membrana tympani is drawn forcibly inwards, the lower end of the malleus is drawn with it, while the upper end remains nearer its normal position, so causing the posterior fold of the membrana tympani to become more prominent, and we have at once an abnormal inward bulging of the membrana tympani. Of course, such a condition of the membrana tympani can be produced by causes other than a contraction of the tensor tympani, but we possess very positive means of investigation for distinguishing other abnormalities which show the same pathognomonic appearances on the part of the membrana, and by exclusion we can make our diagnosis sure.

Since I have here considered the greater prominence of the folds of the membrane as a diagnostic symptom of the sunken condition, and as a phenomenon related to shortening of the tendon of the tensor tympani, I might also describe many others which are all caused by shortening of the tendon.

We know how to recognize and appreciate them, and, by a minute examination and some diagnostic acuteness, should seldom remain in doubt.

In this connection, I might mention a few of the symptoms which are here of great diagnostic value, but which, as it seems to me, have not been sufficiently appreciated by my colleagues.

These appearances are as follows: The handle of the malleus appears broader, the membrana tympani is twisted (*torquirt sein*), the axis-band of the malleus becomes more conspicuous, and the membrana tympani returns more or less rapidly, by retraction, into its former abnormal position, after the application of the air-douche had caused it to bulge outward."

The eighth cause is "Aspergillus in the auditory canal or on the membrana tympani;" this is a mould or fungus which causes inflammation with a discharge like otorrhœa, or a whitish membrane like cerumen or cholesterolin. In every obstinate case of inflammation of the auditory canal, we should carefully examine the discharged material under the microscope to be certain of the diagnosis. The symptoms are fulness of the ear, constant tinnitus aurium, and pain of a dull heavy character.‡

PATHOLOGY.

We have noticed, under causes, that "tinnitus aurium" results from affections of the external ear, on both the anterior and posterior surface of the

* Turnbull on Diseases of the Ear, p. 79.

† Tenotomy of the Tensor Tympani, by Prof. Joseph Gruber, M.D. Translated by Charles S. Turnbull, M.D., Phila., 1873, p. 23.

‡ See paper by the writer on "Aspergillus," in Transactions Med. Soc. of the State of Pennsylvania, 1873. Diseases of the Ear, pp. 104-

membrana tympani, cavity of the tympanum or middle ear, and Eustachian tube. The noises in the internal ear have also been confounded with an affection of the brain itself or its coverings. It is possible to have ringing noises in the ear even when there is, so far as our examinations can penetrate, no organic change in any portion of the ear.

In the post-mortem examination of persons who have suffered from "tinnitus" for a long period without any disease of the ear before referred to, the appearances that have been found on dissection of the petrous bone by Ménière,* Politzer,† Schwartz,‡ and Hinton,§ are disease of the semicircular canals, ecchymosis in the vestibule, hyperæmia of the cochlea, general enlargement and fulness of the vessels of the labyrinth.

We must therefore for the present come to the conclusion that the semicircular canals and vestibule are the seat of the diseased conditions above described, with now and then apoplexy or endolabyrinthine fulness of the labyrinth, showing more or less pressure within its walls or irritation of the auditory nerve. In proof of this, cases are on record where the patient suffered for years with constant noises, and yet when the ears were examined by careful dissection of the temporal bones, etc., nothing abnormal was found.

TREATMENT.

In the first class of cases to which we referred—namely, pressure from cerumen upon the membrana tympani—the treatment in the great majority of cases is simply to remove the offending cause by means of the injection of tepid water in which there is a portion of soda. Numerous cases of this class are relieved by this simple procedure; many of them are of a distressing character.

The second variety is caused by excessive growth of stiff hairs in the meatus. The treatment consists in carefully cutting the hairs close up to their point of exit by means of curved scissors, and removing each one when cut. The objection to plucking them out is that it will frequently cause an abscess at the termination of the hair-follicle. Another form of this same variety is when a hair becomes detached and falls upon the membrana tympani, from which it must be removed by means of a camel's-hair pencil slightly moistened in glycerin.

The patient referred to in whom pus from an abscess was washed to the surface of the membrana tympani was a distinguished hospital-surgeon, who caused it by attempting to wash out his own ear. When the syringe was properly employed in the hands of another, the pus was removed, and the tinnitus ceased.

The third variety of causes is when adhesive mucus is on the posterior surface of the membrana tympani, middle ear, or mastoid cells. This is removed by a few blasts from Politzer's air-bag or douche; if these means are not effectual, paracentesis of the membrana tympani and washing out the middle ear

with a solution of biborate or sulphocarbonate of sodium in warm water. At the same time attention must be given to the naso-pharyngeal region with the use of the nasal douche, sprays, and gargles.

In the fourth variety, or foreign bodies in the Eustachian tube, the treatment will be to reverse the action of the air-bag by withdrawing the air by means of an elastic catheter in the pharyngeal orifice of the tube, and compressing the nostrils, or by means of bag and curved glass tube introduced by the mouth as near as possible to the mouth of the tube, and rarefying the air. Should the foreign body produce inflammation, with effusion bulging of the membrane, its escape should be facilitated by perforation of the membrane by an aspirator-needle.

In the fifth form, or pulsating tinnitus, the result of some alteration in the blood-vessels, anæmia, or excessive action of the heart, we must try compression of the temporal or carotid, diminishing the frequency of the heart's action by aconite or digitalis; or, if the patient is anæmic, administer the salts of manganese, or the lactate or citrate of iron, with good nourishing diet and out-door exercise, avoiding all forms of excitement, as dancing, violent exercise, or mental effort.

In the sixth class we must make a careful diagnosis by exclusion to discover whether we have excitement of the brain causing subjective noises, or on the other hand the exhaustion from over-effort of the brain or some drain upon the nervous system; for in the first instance we resort to large doses of bromide of potassium, or, if there is any suspicion of syphilitic complication, add the iodide of potassium until we produce bromidism on the one hand or iodidism on the other, with its characteristic eruption.

If it is the second instance from exhaustion, we resort to a solution of phosphoric acid employed in the form of a lemonade, or to the phosphites or hypo-phosphites, in conjunction with strychnia or its salts, with the use of the galvanic current to complete the cure.

In the seventh class of cases the operation of tenotomy of the tensor tympani is to be recommended, and the mode of operation is that of Dr. Fr. E. Weber-Liel,|| of Berlin, which we have here employed in a number of cases with more or less success, depending upon the cause.

In the eighth class of cases, which are generally the result of a patulous condition of the orifice of the Eustachian tube, the remedy should be the application of a powerful solution of nitrate of silver or sulphate of copper or carbolic acid to the mouth of the tube, and washing by the use of the double Eustachian catheter, with the internal use of strychnia, to stimulate the muscle to contract and close the orifice.

The ninth class, or "Aspergillus;" the vegetable parasite or fungi is to be removed by the forceps and a warm saturated solution of sulphite of soda, and the discharge of mucus or serous fluid is to be

checked by the use of an injection of a strong solution of sulphocarbonate of zinc. A number of these cases of a mild character we have treated after the summer season in patients who have allowed the sea-water to dampen the hair and pass into the ears. In these cases a mild solution of an astringent, acetate of lead or sulphate of zinc, will remove all the symptoms of itching, deafness, and distressing tinnitus, in a very short time.

EMBOLI OF THE RIGHT MIDDLE CEREBRAL ARTERY; LEFT HEMIPLEGIA, AND DEATH,

PRECEDED FOR THREE MONTHS BY MUSCULAR AND OTHER PAINS PROBABLY DUE TO EMBOLI OF THE REGIONS THUS AFFECTED.

BY S. WEIR MITCHELL, M.D.

MISS B., æt. 32, at the age of 16 years had an attack of inflammatory rheumatism, resulting in disease of the heart. She came under my care at the age of 23, and thereafter suffered at intervals from violent palpitation of the heart. At this time she was gaining in flesh, and was of a ruddy complexion. The heart was violent in action, and beat with a strong, decisive throb, and with the firm blow of an enlarged organ. The apex-beat was felt over a large area, and most distinctly an inch and a half below and an inch to the left of the nipple. At this point there was a strong, clear murmur, which never changed character, and which entirely replaced the systolic sound. There was, therefore, no doubt as to there being regurgitant disease of the mitral valve, with no other valvular lesion. As years went on, the frequent flushes and consequent vertigo became more and more annoying, and the signs of enlargement more decided. Many forms of medication were tried and in turn failed, when at last permanent comfort resulted from the use of a course of milk-cure, under which the flushes lessened, the heart became tranquil, and she lost some fifteen pounds of weight in six weeks. Thenceforward, until a year ago, she remained in fair health. At this time, in May, 1873, she began to lose weight, and to suffer in strength and appetite. Despite tonics and change of air, and with no appreciable new disease of heart, lung, or kidneys, she continued to lose ground, the murmur at the left apex growing more and more noisy. About three months ago Miss B. was suddenly seized with acute pain in the left calf. It yielded to local treatment, but was followed for two months, at intervals of from a few hours to days, by a strange succession of like pains, sometimes in the muscular masses of the legs below the knee, once or twice in the feet, then in the neck, the arms, and the hands, so that she was rarely long free of pain. With these sudden attacks there was rarely any fever. They came suddenly, grew worse for hours or for a day, were accompanied with most variable amounts of local tenderness, and sometimes with slight swelling, and then by degrees faded, to re-appear elsewhere. At length she had two large blotches of extravasated blood, like subcutaneous bruise-marks, on the left hand, with intense aching pain. The week after, the right calf showed a like appearance, and once the left cheek and right hand. It was, of course, natural to regard a person once the victim of rheumatism as likely again to suffer from it, but the absence of high fever, and a temperature never above 100° F., there being at no time any joint-disease, puzzled me extremely. On the 8th of April she had quite suddenly, while in bed, a sense of vertigo, and soon after noticed loss of vision

in the lower half of the left visual field. A careful ophthalmoscopic study showed only slight haziness along the arteries and veins of both disks, but no swelling of either. I left her feeling myself most uneasy in view of the strong probability of embolism. Next morning she was in a stupor, and had absolute hemiplegia of the left side, including the face, and also some nystagmus, the eyes twitching, and not passing to the right of the middle line. The reflex acts were marked, and sensation seemed, and proved afterwards, to be unaltered. After a few days, consciousness returned, and she became clear in mind, but with no tendency to speak unless addressed. A week later she began to talk more, and thenceforward grew unusually irritable, but had only once some pain in the left leg. Three weeks after her attack, the stupor, returning, slowly deepened, until, four weeks from her first palsy, she died quietly.

I should add that twice last fall she fell suddenly in the street, her limbs simply giving way, with no accompanying brain-symptoms. I should also add that twice during her long illness the pains came on afresh after unusual exertion. There was at no time any albuminuria.

At the post-mortem section, which was necessarily limited, we found one lip of the mitral valve very rough, and covered with long beaded vegetations or studded with tiny morsels of scarcely adherent fibrin. Nearly all were small as shot, and seemed ready to drop off at a touch. The heart was of normal size, and not fatty; the other valves healthy. The left side of the brain was sound, except for a small clot at the posterior aspect of the posterior lobe, beneath the membranes. The right middle lobe was softened, and thoroughly diffused as far out as the gray matter, and the softening extended deep into the corpus striatum. Dr. Gerhard, who kindly made the examination, found the right middle cerebral artery plugged by a series of minute shot-like emboli, which accurately corresponded to those on the mitral valve. The lowest was just outside of the circle of Willis.

The brain-symptoms in this case were sufficiently accounted for by the state of the cardiac valves, and when I saw the heart it occurred to me that the pains in the muscles and areolar spaces—pains which, to Dr. John Meigs, who also saw the case, and to myself, were strange and clinically inexplicable—must have been due to the impaction in the tissues of little emboli. Where they filled up vessels near the surface, the usual extravasation was seen beyond the point obstructed. Where deep in the tissues the vascular results were hidden, but in both cases alike pain resulted,—a pain which was perhaps the more severely felt, owing to the temperament of the sufferer. As the case now appears to me, I have little doubt that this was the correct reading of it.

I may add, as matter of interest, that for three weeks after her paralysis the nails grew on neither hand, and that for the last week they were so nearly alike on both as to make me unable to decide which grew the faster. It is curious that the cases of exception to the non-growth for a time of the nails on the palsied side have most frequently been left hemiplegias.

I supposed that I should find, in the literature of emboli, many cases like the one I have stated; but while embolic and thrombic plugging of large vessels seem common enough, instances of multiple emboli in minute arteries seem rare.

Our poverty in cases of this kind is certainly

curious. When once attention shall have been fully directed to them, they will possibly prove less rare than they seem to be. When a person has had rheumatism, any long sequence of pains and tenderness with pain is very apt to be taken for some form of the old enemy, and we may thus be led, as I was in my own case, to overlook the true parentage.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.*

A VISIT to the upper surgical wards, at present under the care of Dr. Hewson, shows but few cases of importance under treatment. An operation was recently performed for the relief of cancer involving the glands of the inguinal region. The disease was in the ulcerative stage, and involved the glands and tissues over an area of about six square inches. The operation consisted in a careful dissection by means of a scalpel, aided by the fingers of the operator, and extending down to the sheath of the femoral vessels.

A few incisions were made to relieve tension, and the two or three superficial vessels which had been severed were secured by torsion, no ligature being used. The wound was closed by sutures, and the thigh was strongly flexed upon the abdomen.

It was hoped that rapid union would have taken place, but, as the flaps showed a tendency to slough, the sutures were removed after a day or two, and when we saw the case, a week subsequent to the operation, union by granulation was proceeding nicely.

The dressing used in this case was oakum soaked in a solution of carbolic acid (3i ad Oj aq.), over which finely-powdered dry clay was sprinkled, and as a covering to the whole a paste of the latter.

Suppuration from so large a surface being somewhat profuse, a means of exit for the fluid product was afforded by the use of an india-rubber drainage-tube. In order to keep the wounded parts in apposition, the thigh remained flexed upon the abdomen, and was supported in this position by an ingenious application of the anterior wire splint, suspended by a "gallows." This arrangement permits such movements of the patient as are necessary for defecation, etc., to be made without disturbing the dressing.

A very successful case of skin-grafting was performed by Dr. H. on an ulcer of the leg, which had long defied all other methods of treatment. The "grafts" were in reality only scrapings from the deeper layer of epithelium on the patient's instep, which flourished amazingly when transplanted.

In the lower surgical wards, under Dr. Hunt's care, there have been lately a number of cases of erysipelas, several quite severe, but none fatal: the treatment is similar to that employed in the medical ward. As a dressing for ordinary fractures of the lower limbs, Dr. Hunt prefers the fracture-box, the limb being placed on a small pillow, which is enclosed in the box. Where the fracture is compound, the same box is used, but is filled with bran, that portion nearest the wound being mixed with carbolic acid powder. This dressing is neat, and by its use not only are the discharges absorbed and disinfected as they escape, but the wound may be inspected and cleansed at any moment without disturbing the limb in the least.

Fractures in the continuity of the femur are treated

by Dr. Hunt with the aid of long sand-bags placed on either side of the limb, extension being provided for by strips of plaster attached to either side of the leg, and meeting like a stirrup below the sole of the foot, to which a small cord is fastened, passing over a pulley, and having an appropriate weight at the end. In one of the wards we observed an unusual form of fracture in a child of seven years, involving the neck of the humerus, the head of which had sustained a luxation forwards; a rectangular splint had been applied after reduction of the luxation.

In the medical ward there are now under Dr. J. A. Meigs's care a number of cases of acute rheumatism; heart-complications have been unusual lately, and only one or two patients are at present suffering from such troubles. The usual treatment is the bromide of ammonium in ten- to fifteen-grain doses three or more times daily. This is frequently combined with the acetate of potassium. When violent action of the heart co-exists, or when valvular lesions are threatened, tincture of digitalis in ten-drop doses *ter die* is employed, and in the latter case sinapisms or belladonna plasters are applied over the præcordia.

Several cases of erysipelas are under treatment; one of these is remarkable for having undergone a number of relapses. The treatment in these cases is invariably the tinct. ferri chlor. in doses of twenty drops frequently repeated, often every two hours. Slippery elm mucilage is used as an outward application, and during convalescence quinia is freely administered. There are at present in the ward a number of individual cases of interest. Among these is one of congestion of the spinal cord in a young woman, who, having been exposed to cold and dampness during her menstrual period, was suddenly seized with loss of power in the muscles of the back, so that she was unable to hold herself in an erect position. Later, she began to experience stiffness in the neck, and some six months after the exposure she began to lose power in her limbs. When admitted to the hospital she could walk with great difficulty. Dry cups were applied to the spine, and a pill of ext. belladonnæ, gr. $\frac{1}{2}$, quiniæ sulph., gr. ii, *ter die*, under the influence of which she is slowly improving.

In the men's ward there is a case of dilation of the stomach, accompanied by occasional paroxysms of severe epigastric pain. Any food taken causes "heaviness," and nausea without vomiting is frequent. Examination at the time of the patient's admission showed sarcinæ and torulæ in the contents of the stomach. The case is a chronic one, and has been in and out of the hospital several times. Various remedies, as strychnia, argenti nitras, etc., have been used without permanent success. At present the patient is taking pepsin, gr. v, with acid. nitromuriat. dil., gtt. x, t. d. in water, under the use of which he seems to be slowly improving.

A case of syphilitic hemiplegia has been under treatment in the ward for some six weeks. The paralysis is partial, and affects the left leg and arm. It came on suddenly, without loss of consciousness or even giddiness. The patient could, on admission, walk without assistance, but dragged the affected limb. He could also use the arm, but lacked firmness of grasp. Under the use of ten grains potassii iodid. t. d., with the application of the induced current, he is becoming rapidly better. The finger-nails, which have been stained, show no want of growth on the affected side.

A case of diabetes mellitus of about ten months' duration is at present under treatment in the male ward. The patient, who was formerly quite a robust man weighing one hundred and eighty pounds, has lost flesh so that he now weighs but one hundred and thirty-five pounds. His appetite is voracious, and he suffers from intense thirst, not alleviated by large quantities of

* We are indebted to the courtesy of the Attending and Resident Staff for the opportunity of making these notes.

water, which only causes nausea. His skin is dry and unspirable; he suffers from cramps in his legs, and is quite weak. The urine on admission had a specific gravity of 1034, which has fallen in the few days he has been under treatment to 1032, while the amount excreted in twenty-four hours has fallen from seventeen to fifteen pints. No albumen has been detected at any time. The treatment has consisted in opii gr. i, ext. belladon. gr. $\frac{1}{8}$, *ter die*.

TRANSLATIONS.

IGNIPUNCTURE.—“*Quod remedium non sanat, ferrum sanat; quod ferrum non sanat, ignis sanat; quod ignis non sanat, insanabile dici debet.*” Dr. Paul Trapenard, prefixing his brochure of seventy-two pages (*L'ignipuncture—De ses différents Emplois—De son Indication spéciale dans les Tumeurs blanches*) by the above aphorism of Hippocrates, gives the results of his observations with this method of using fire. The discovery is due to Prof. Richet, whose pupil M. Trapenard was during five years.

Hitherto cauterization has been simply destructive or revulsive. A. *Destructive* action upon the tissues, to annihilate the dangerous effects of a known or of an inoculated virus, to modify fungous uterine ulcers, to combat hospital-gangrene, to cut down exuberant fungosities in general. The result aimed at has been the profound disorganization of the part, and the formation of an eschar. B. A *revulsive effect*, to displace deep-seated irritation after the manner of a blister. The practice of searing the skin over a joint affected with white swelling has been attended with good results. Rebellious neuralgias have been treated successfully by points of fire applied to the surface, etc. To these destructive and revulsive actions of cauterization M. Richet has added a *limiting* action. Ignipuncture, then, is a special kind of cauterization, of which the action is revulsive, substitutive, very slightly destructive, but *limiting*, and sometimes eliminative. It has been found useful in a multitude of affections, and particularly in white swelling. It consists in plunging a little cautery at various points into the bone, into the diseased joint, into the tissues, that are to be modified. The instrument is composed of four parts. 1. A handle, consisting of a metal piece sunk into a bit of wood twelve to fifteen centimetres in length. 2. A steel rod, fitting a socket in the handle. This may be fixed with a spring, so that the same handle serves for several cauteries. 3. A steel ball, two centimetres in diameter, at the end of the rod, which it, so to speak, reinforces. This is to concentrate the heat and hold it in reserve. 4. A needle of platinum, varying in size and length with the tissues to be acted upon. This is screwed into the ball. Steel so changes its color at different temperatures that it shows at a glance when the proper heat is reached. Six to eight cauteries are required. A white-heat enables the needle to penetrate with greater ease, and is less painful. In opening cysts a cherry-red is better, as the eschar becomes adherent to the cautery, and is withdrawn with it. Each needle is entered at a single thrust, and at once withdrawn, the points selected having been marked with ink beforehand.

As a rule, chloroform is not given. The pain is very intense, but of brief duration. For three days or less, wet compresses are to be applied to the cauterized parts. The action is—1, revulsive, a quality which it shares with cauterization in general; 2, evacuant; 3, limiting or modifying. The latter raises ignipuncture into a method. The tissues, in the lines of puncture are profoundly affected by heat. At the end of a few days suppuration is established. This diminishes little by

little, ceases, and the fistulous orifices close and become depressed. Meanwhile, the tumor diminishes. Cicatricial tissue occupies the lines of cauterization. These extend in various directions; hence arises a sort of *cirrhosis* of the tumor as contraction takes place, and a continuous and progressive compression of the affected structures comprised within those inodular brils.

White swelling (*tumeur blanche*) was the term applied by Richard Wiseman, in 1734, to a certain class of scrofulous affections of the joints. It is to-day restricted to affections of a purely scrofulous nature; nevertheless it is a generic term, under which are included chronic synovitis, chronic inflammation of bone, and chronic osteo-synovitis of this kind.

The effect of ignipuncture is obvious, safe, and of incontestable benefit—1, in pseudo-membranous synovitis in the second stage; 2, in fungous synovitis and osteo-synovitis in the second stage; 3, in progressive inflammation of the bone, whatever its nature.

M. Richet employed this method in a terrible case of necrosis of the jaw from phosphorus, in which, after the removal of the sequestrum, the disease continued, with the effect of arresting it. It is to be regretted that this case passed from under observation during the treatment.

Two cases of acute bronchocoele are reported, in which cures were effected by ignipuncture.

It is recommended in hypertrophic elongation of the neck of the uterus, and has been successfully employed in chronic ganglionic enlargements, in hypertrophic acne, and in tubercular disease of the testicle. Ignipuncture is inapplicable to aneurisms and to varicose tumors.
